We report the case of a 25-year-old female patient, diagnosed at birth with transposition of great arteries and peri membranous VSD, who didn't benefit from surgical correction for the congenital malformation. 10 years before admission the patient developed secondary hypertension and Eisenmenger syndrome, for which she was receiving chronic treatment with vasodilators Bosentan 125 mg b.i.d. and Sildenafil 20 mg t.i.d. At admission the patient presented for severe coughing with important hemoptysis, fatigability and shortness of breath at mild effort, myalgia, headaches and vertigo.

The physical examination showed a mildly altered general status, absence of fever, cyanosis, digital clubbing, congestive sclerae, heart rate 100 bpm, systolic murmur grade IV/VI, accentuation of the 2nd heart sound, BP 140/90 mmHg, SpO_2 68% in room air.

The electrocardiogram revealed: sinusal rhythm, 100 bpm, QRS axis-150 degrees, prominent P wave, 1st degree AV block, major RBBB (fig. 1).

We performed the 6-minute walking test with the following pretest parameters: SpO_2 65%, HR 100 bpm, BP 140/90 mmHg. During the test the patient walked 250 m, with the aggravation of the cyanosis, a 14/20 dyspnea on the Borg scale, a SpO_2 of 60%, HR 120/min, BP 130/90 mmHg.

The blood tests showed erythrocytosis (Hb 20g/dL, Ht 69%, RBC 9.3 million/mm^3), secondary thrombocytopenia (52,000/mm^3), iron deficiency (iron 16 µg/dL, ferritin 11 ng/dL).

The transthoracic echocardiography (TTE) revealed atrioventricular concordance and ventriculoarterial discordance, a large subaortic VSD (30 mm) with bidirectional shunt, preserved systolic function of the left and right ventricles, grade III tricuspid regurgitation (the septal cusp of the valve, floats in the left ventricle through the defect, during diastole), severe secondary pulmonary hypertension (sPAP 113 mmHg, mPAP 70 mmHg) (fig.2).

Right heart catheterization confirmed the pulmonary hypertension with increased pressions (mPAP 114 mmHg, sPAP 173 mmHg) and increased pulmonary vascular resistance (PVR 40 uW, 60 uWi and a PVR/SVR of 1.4).

One month before admission, the patient had undergone a thoracoabdominal CT examination, which revealed a tumoral mass of 50/35/40 mm, with delimitation of hypodense necrosis areas, on the topography of the suprarenal gland and splenic venous hemangiomas (fig. 3).

Considering the CT findings, we decided to investigate the secretor nature of the suprarenal tumor. The serum ACTH was slightly but inconclusively increased (55.2 pg/nL), serum cortisol morning/night ratio was normal (16.7µg/mL/6.78µg/mL), as well as free urinary cortisol (113.94 µg/24h) and metanephrine values (309 µg/24h). All these results pleaded for a nonfunctioning adrenal incidentaloma. After multidisciplinary evaluation (endocrinologist, surgeon and the anesthesiologist we decided to postpone the surgery and monitor the evolution of the tumor every 3 months, due to the high anesthetic risks.

Management of the patient consisted in phlebotomy, with the evacuation of 400 mL of blood, with normalization of red cell and platelets values. In addition to the vasodilatation therapy we added low doses of diuretics, which improved the dyspnea and also oral iron supplementation.

Fig. 2. TTE-a. Parasternal long axis view- important ventricular septal defect, with bidirectional shunt (white arrow). b. Apical 4 chamber view-the septal cusp of the tricuspid valve, floats in the left ventricle, during diastole (white arrow). c. Parasternal short axis view at the base of the great vessels-the aortic (white arrow) and pulmonary valves (red arrow) can be seen in the same echocardiographic plane (typical image for TGA).

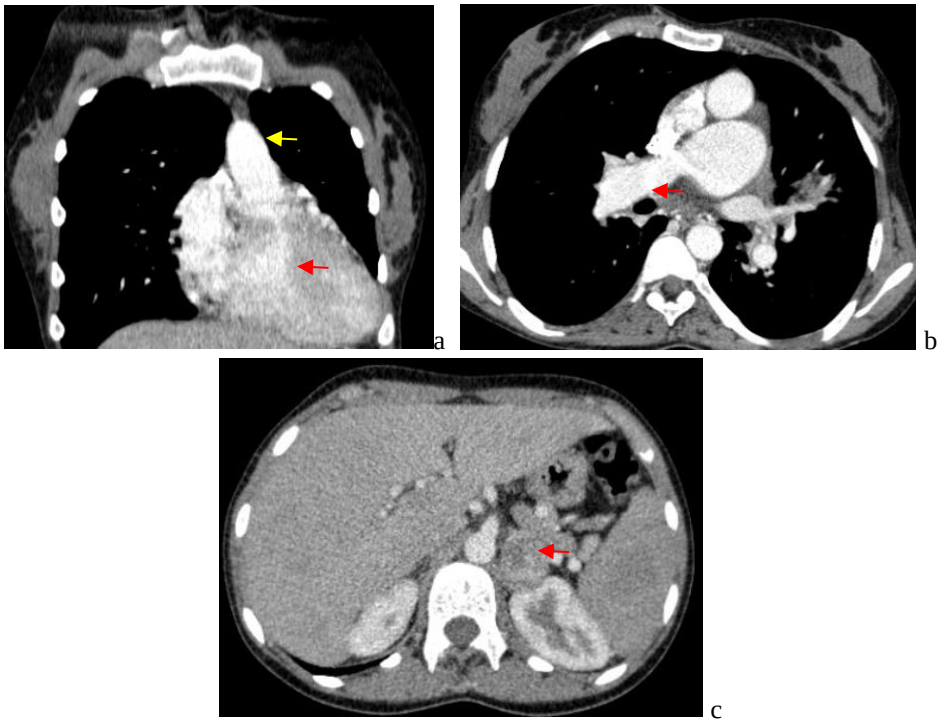

Fig. 3. Thoracic CT with intravenous contrast presents in arterial phase an important septal defect (red arrow), the aorta emerging the right ventricle (yellow arrow) (a) and the pulmonary artery emerging the left ventricle (red arrow) (b). Abdominal CT reveals a tumoral mass at the level of the left adrenal gland with inhomogeneous contrast enhancement (red arrow) (c).

DISCUSSION

This case represents a real exception from the typical natural history of patients with transposition with the great arteries. Most of the studies regarding this pathology date from the pre-surgical era, but they report a 90% mortality rate at 1 year after birth (2). This prognostic can be improved by the association of another defect that permits the communication of the blood between the two circulations, such as atrial septal defect (ASD), persistent ductus arteriosus and VSD. The best prognosis can be found in the patients with VSD and pulmonary sub valvular stenosis, when the debit in the 2 circulations is equilibrated with a life expectancy of 3 years. In the case of our patient, where only a ventricular septal defect is associated, the life expectancy is somewhat lower, but there are still reported cases of patients reaching adolescence or even the 3rd or 4th decade of life (1, 2).

The only curative treatment for patients with transposition of the great arteries remains the surgical correction in the neonatal period through arterial switch techniques and the correction of associated malformations (1). In our case, by presenting secondary pulmonary hypertension, a correction procedure is not indicated, and the pri-

mary option remains heart-lung transplantation. However, the 10-year life expectancy in patients who undergone transplant is only 30-40%, which is inferior to the life expectancy of patients receiving pulmonary vasodilatation therapy, thus the right timing for the surgery is debatable (3).

In the case of unoperated patients, with severe pulmonary hypertension, the therapeutic strategy consists in using vasoactive drugs that target, together with the prevention of the complications of hypoxemia (erythrocytosis, thrombocytopenia, coagulation disorders) (4, 5, 6). Our patient, presented with moderate hyper viscosity symptoms (headaches, myalgia) and important erythrocytosis, prompting us to perform a phlebotomy with the removal of 400 mL of blood together with isovolumic fluid replacement, with a good clinical and hematological outcome. Regular phlebotomies are not indicated, as they induce iron deficiency and microcytosis, which are associated with cerebrovascular events (4). The main classes of vasoactive therapy are endothelin receptor antagonists (Bosentan) (7), phosphodiesterase type 5 inhibitors (Sildenafil) (8), and prostacyclin derivates. In this case the patient already received chronic treatment with high doses of Bosentan and Sildenafil, with low efficiency on the symptomatology. Consequently, additional treatment with prostanoids should be tried, as current studies with intravenous epoprostenol showed improvement of the hemodynamics and of the exercise capacity, but with increased risk of paradoxical embolism and infections, due to the presence of a central venous catheter (9). Studies with other prostacyclin analogs such as subcutaneous treprostinil or oral selexipag, which are used for idiopathic pulmonary hypertension, are in the incipient phases, with favorable results (10, 11).

Another particularity of the case was the presence of the adrenal incidentaloma (AI), which posed problems regarding the necessity of a surgical intervention. Current literature suggests excision at a cut-off to 4 cm as most adrenocortical carcinomas (ACC) are > 4 cm in size. Also, this cut-off value provided a good sensitivity (93%) in predicting malignant processes; nevertheless, the specificity is a bit low (42%), as a result to the low prevalence of ACC (12).

Non-cardiac surgery for patients with Eisenmenger syndrome is a very controversial topic, due to the high perioperative death which is up to 19%. Hematocrit higher than 60%, arterial oxygen saturation lower than 80%, right ventricular hypertension, syncopal episode and a fixed pulmonary hypertension, not responsive to oxygen represent poor prognosis factors (13). The key to the anesthetic management of patients with ES is to maintain the balance between pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR) during anesthetic induction, together with appropriate monitoring (13, 14). In order to reduce the elevated PVR patients should continue the chronic vasodilatation therapy in the perioperative period, with inhaled pulmonary vasodilators (nitric oxide, epoprostenol) used during the procedure. Another important problem is the hypotension which appears as a side effect of induction agents, which can increase the right-left shunt and the right ventricular dysfunction during the procedure, therefore vasopressor treatment should be associated during induction. Traditionally, general anesthesia has been recommended for these

patients because the relative sympathectomy that occurs with regional anesthesia would tend to decrease SVR (14). However, several cases were reported that documented the relative safety of epidural anesthesia for ES patients (15).

In the case of our patient we decided that a watch-and-wait approach is better for the management of the adrenal incidentaloma, deciding on careful imagistic monitoring every 3 months and hormonal evaluation annually, with the possibility of a surgical approach if the tumor changes in size or shows radiological characteristics of an adrenocortical carcinoma.

CONCLUSIONS

This case shows a rare presentation of an uncorrected cardiac congenital disease, with a natural evolution towards severe pulmonary hypertension and Eisenmenger syndrome. As a result, management of these patients is complex, requires regular and careful monitoring and it focuses both on the vasoactive, but also on the management of erythrocytosis, thrombocytopenia and the coagulation disorders.

The association of the adrenal incidentaloma poses additional problems regarding the management of the patient. Due to the high risk posed by general anesthesia, a multidisciplinary team (cardiologist, endocrinologist, radiologist, surgeon, and anesthesiologist) was required in order to decide on the proper approach and follow-up for the adrenal mass.

NEWS

IS LIVER-LIMITED DISEASE IN METASTATIC COLORECTAL CANCER A PROGNOSTIC FACTOR?

Approximate 44-77% of colorectal cancer patients develop liver metastasis, one of the most frequently involved sites. Among these patients, only 10-30% have a potentially resectable disease that can be treated with curative intent. The resection of the liver metastasis leads to 5-year survival rates of up to 40%. Liver-limited disease (LLD) was investigated as prognostic and predictive factor in patients with initially unresectable disease treated with chemotherapy (FOLFIRI) and targeted therapy: cetuximab (anti-EGFR) or bevacizumab (anti-VEGF) in the FIRE-3 trial. Of 400 patients with RAS wild type tumors included in the analysis, 133 (33.3%) had LLD and 267 (66.8%) had non-LLD. Median overall survival (OS) was significantly longer in LLD compared to non-LLD patients (36.0 vs. 25.4 months) proving that LLD status is an independent prognostic factor in patients with metastatic colorectal cancer treated with targeted therapy and standard chemotherapy. About the predictive relevance of LLD status, the data from the analysis suggest that FOLFIRI and cetuximab improve overall survival and treatment response compared with bevacizumab regardless of the status of LLD (Julian Walter Holch, Ingrid Ricard, Sebastian Stintzing *et al*. Relevance of liver-limited disease in metastatic colorectal cancer: Subgroup findings of the FIRE-3/AIO KRK0306 trial. IJC DOI: 10.1002/ijc.31114).

ATOPIC DISEASES AND INTESTINAL HELMINTH INFECTIONS (Abstract): The purpose of the current study was to examine the relationship between past and current intestinal helminth infections, and asthma, allergic rhino-conjunctivitis, and atopic dermatitis. **Material and method**: The study was performed on 84 patients aged 2-18 years with a mean of 9.31 ± 3.75 years. Helminth infection was determined by stool examinations and questionnaire. Asthma was diagnosed by spirometry, atopic dermatitis and allergic rhino-conjunctivitis by skin prick testing. **Results**: Stool examinations revealed infection with *A. lumbricoides* in 5.95% of cases and *E. vermicularis* in 4.76% of cases. 8 patients had positive tests for at least a helminth. The most frequent respiratory symptoms were caught, wheezing and dispneea. Spirometry showed anormal results in 4.76% of patients and skin tests were positive in 20.24% of cases. 11 patients were diagnosed with allergic rhinoconjunctivitis and 5 with atopic dermatitis. A history of infection with *E. vermicularis* was associated with increased risk of atopic dermatitis (OR 1.86), asthma (OR 2.11), and allergic rhinoconjunctivitis (OR 1.34), and a positive stool examination for *A. lumbricoides* was negatively associated with asthma (OR 2.60). **Conclusions**: Current *A. lumbricoides* infection protects against asthma while past infection with *E. vermicularis* are risk factors for allergic rhinoconjunctivitis, asthma and atopic dermatitis. Interactions depend on the type of helminth and time of infestation. **Key words**: ASTHMA, ALLERGIC RHINOCONJUNCTIVITIS, ATOPIC DERMATITIS, HELMINTHS

Observaţia conform căreia în ţările dezvoltate se înregistrează o prevalenţă ridicată a afecţiunilor atopice şi o incidenţă scăzută a helmintiazei intestinale, spre deosebire de ţările în curs de dezvoltare în care situaţia este inversă, a condus la ipoteza existenţei unei asocieri între cele două fenomene. Deşi studiile de specialitate au demonstrat că expunerea la infecţii parazitare în prima copilărie reduce riscul de atopie, relaţia dintre afecţiunile alergice şi infecţia cu helminţi rămâne insuficient cunoscută şi deci, controversată (1,2).

Majoritatea studiilor din literatura de specialitate au încercat să elucideze corelaţia dintre helmintiaza intestinală şi astmul bronşic, existând puţine informaţii certe cu privire la asocierea cu alte afecţiuni atopice, cum ar fi dermatita sau rinoconjunctivita alergică. Mai mult decât atât, s-a analizat expunerea curentă la helminţi, ceea ce face dificilă investigarea secvenţialităţii temporale a celor două fenomene (3).

Studiul de faţă are drept obiectiv investigarea asocierii dintre infecţia curentă şi în antecedente cu helminţi şi prevalenţa ast-

mului, dermatitei atopice şi rinoconjunctivitei alergice la copii internaţi cu patologie respiratorie în clinicile de pediatrie din cadrul Spitalului Clinic de Urgenţă pentru copii „Sf. Maria" Iaşi în perioada 2007--2010. Concomitent au fost analizate contribuţiile altor factori de risc în determinarea afecţiunilor atopice descrise în literatura de specialitate.

MATERIAL ŞI METODĂ

Studiul curent s-a efectuat pe un lot format din 84 de pacienţi diagnosticaţi cu afecţiuni respiratorii în intervalul 2007-2010, spitalizaţi în clinicile de pediatrie din cadrul Spitalului Clinic de Urgenţă pentru copii „Sf. Maria" Iaşi. Etapele alcătuirii lotului şi analiza foilor de observaţie s-au desfăşurat în conformitate cu legislaţia medicală în vigoare.

Toţi copiii incluşi în lotul de studiu au fost investigaţi spirometric, înainte şi după efort, alergologic (*prick-test*) şi coproparazitologic. Adiţional, aparţinătorii au fost chestionaţi cu privire la factorii de risc ai sensibilizării alergice: administrarea de antibiotice în primul an de viaţă, contactul cu animalele de companie, prezenţa refluxului gastro-esofagian, expunerea la fum de ţigară, alimentaţia cu lapte de vacă.

Atopia a fost definită ca prezenţa unui test cutanat pozitiv la cel puţin unul din alergenii aplicaţi. Testul alergologic a implicat utilizarea a 7 alergeni: *Dermatophagoides pteronyssinus, Dermatophagoides farinale,* păr de pisică, polen mixt de copaci, polen mixt de iarnă, *Alternaria alternata* şi acarieni. Testul alergologic a fost realizat pe faţa ventrală a antebraţului stâng, iar răspunsul cutanat a fost cuantificat după 15 minute, luându-se în considerare cea mai mare papulă (diametru ≥ 3 mm), în absenţa reactivităţii semnificative. Pentru a demonstra hiperreactivitatea bronşică s-a realizat spirometria la 5 şi 10 minute după exerciţiul fizic, conform ghidului American Thoracic Society. Testul a fost considerat pozitiv dacă FEV1 (*forced expiratory volume*) a înregistrat valori mai mici de 70% din valoarea prezisă sau a scăzut cu mai mult de 15% la 5 sau 10 minute după exerciţiul fizic (alergare 6 minute). În acest caz, copilul a primit un bronhodilitator pentru a facilita recuperarea, iar spirometria a fost repetată la 20 minute de la administrarea bronhodilatatorului, pentru a ne asigura de atingerea valorilor bazale. Infecţia cu helminţi a fost confirmată prin certificarea prezenţei de ouă de paraziţi (*Ascaris lumbricoides* sau *Enterobius vermicularis*) la examenul coproparazitologic. În cazul fiecărui subiect s-au analizat antecedentele de infecţii cu helminţi prin chestionarea aparţinătorilor.

Datele obţinute au fost analizate şi exprimate procentual, diferenţele dintre valorile medii ale parametrilor investigaţi au fost analizate prin intermediul testelor *t--Student* şi *ANOVA*, iar asocierile dintre diferiţi factori au fost interpretate cu ajutorul testelor de corelaţie şi regresie. Prelucrarea statistică a fost realizată cu programul *Statistica 8.0.*

REZULTATE

Vârsta medie a pacienţilor incluşi în studiu a fost de 9,31 ani, 57,14% aparţinând sexului masculin, iar 42,86%, sexului feminin. Examenul copro-parazitologic a evidenţiat prezenţa *A. lumbricoides* la 5,95% dintre pacienţi şi a *E. vermicularis* la 4,76%. 8 copii au avut teste pozitive pentru cel puţin

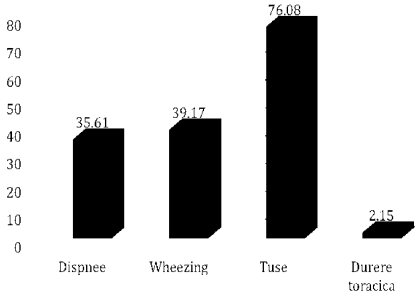

Fig. 1. Simptomele respiratorii întâlnite la pacienţii cuprinşi în lotul de studiu

TABELUL I
Rezultatele regresiei logistice multivariate privind asocierea afecţiuni atopice, infecţie cu helminţi

Variabilă/Factor de risc	Raportul cotelor	Interval de încredere 95%	*p*
Rinoconjunctivită alergică			
Istoric de infecţie cu *E. vermicularis*	1,34	1,00-1,79	0,048
Simptome de reflux gastro-esofagian	1,74	1,24-2,44	0,003
Atopie familială	1,67	1,07-2,59	0,025
Administrarea de antibiotice în primul an de viaţă	1,80	1,28-2,53	0,002
Dermatită atopică			
Istoric de infecţie cu *E. vermicularis*	1,86	1,34-2,58	0,001
Examen coproparazitologic pozitiv pentru *A. lumbricoides*	0,23	0,08-0,68	0,011
Atopie familială	1,56	1,09-2,24	0,017
Administrarea de antibiotice în primul an de viaţă	1,61	1,10-2,35	0,017
Contact cu animale de companie	0,68	0,48-0,98	0,039
Wheezing			
Examen coproparazitologic pozitiv pentru *A. lumbricoides*	2,60	2,00-3,38	0,001
Examen coproparazitologic pozitiv pentru *E. vermicularis*	2,11	1,55-2,86	0,001
Simptome de reflux gastro-esofagian	1,59	1,20-2,11	0,003
Teste spirometrice anormale			
Examen coproparazitologic pozitiv pentru *A. lumbricoides*	6,56	1,30-33,13	0,025
Examen coproparazitologic pozitiv pentru *E. vermicularis*	2,77	1,94-3,97	0,001

un helmint. Dintre simptomele respiratorii, cel mai frecvent s-a întâlnit tusea, urmată de wheezing şi dispnee (fig. 1).

Teste spirometrice anormale au fost întâlnite la 4,76% dintre pacienţi, iar reacţiile cutanate pozitive la 20,24%. 11 pacienţi (13,09%) au prezentat rinoconjunctivită alergică, iar 5 (5,95%) dermatită atopică.

După ajustarea testelor statistice pentru vârstă, sex, mediul de proveniență s-a evidenţiat asocierea istoricului de infecţie cu *E. vermicularis* cu risc crescut de dermatită atopică şi rinoconjunctivită alergică şi a istoricului de infecţie cu *A. lumbricoides,* cu risc de astm bronşic alergic. Prezenţa unui examen copro-parazitologic pozitiv pentru *A. lumbricoides* s-a asociat invers proporţional cu prezenţa dermatitei atopice. Prezenţa rezultatelor pozitive la testele efectuate nu s-a asociat semnificativ cu nici unul dintre helminţi în cazul regresiei multiple (tab. I).

DISCUŢII

Deşi există numeroase studii în literatura de specialitate care demonstrează asocierea inversă între prezenţa infecţiei cu helminţi şi afecţiunile atopice, relaţia dintre cele două afecţiuni este încă incomplet cunoscută şi demonstrată. Literatura de specialitate consultată oferă rezultate contradictorii conform căreia helmintiaza cauzează, inhibă sau chiar nu prezintă o asociere cu afecţiunile atopice (4). Studiul de faţă confirmă existenţa a diferite asocieri între infecţia cu helminţi şi afecţiunile atopice, natura acestora depinzând de tipul infecţiei helmintice şi al atopiei. Concomitent, momentul infecţiei cu helminţi deţine un rol important, aşa după cum o demonstrează analiza informaţiilor obţinute de la aparţinători în absenţa rezultatelor examenelor coproparazitologice anterioare. Această metodă este nespecifică şi are sensibilitate redusă având în vedere lipsa preciziei informaţiilor obţinute, fiind grevată de riscul cuantificării efectului infecţiilor masive. Cu toate acestea, considerăm că rezultatele obţinute constituie un indicator patent al importanţei momentului infectării cu helminţi în determi-

nismul afecţiunilor atopice.

Prezentul studiu demonstrează o asociere inversă între infecţia curentă cu *A. lumbricoides* şi dermatita atopică, sugerând că infecţia cu *A. lumbricoides* ar oferi protecţie împotriva dermatitei atopice. Cu toate acestea, reversul acestei relaţii nu poate fi exclus, în condiţiile în care istoricul de infecţie cu *A. lumbricoides* nu a exercitat nici un efect asupra incidenţei dermatitei atopice. O relaţie inversă, bidirecţională, între infecţia helmintică şi dermatita atopică a fost raportată de Schafer şi colab., care au utilizat rezultatele chestionarelor pentru a determina momentul instalării celor două afecţiuni. Includerea în analiză a secvenţialităţii temporale a condus la concluzia că prezenţa antecedentelelor de infecţie helmintică se corelează invers proporţional cu dermatita atopică, iar antecedentele de dermatită atopică, se asociază negativ cu infecţia helmintică.

Există puţine studii în literatura de specialitate referitoare la relaţia dintre parazitozele intestinale şi dermatita atopică. În cadrul prezentei cercetări am evidenţiat o asociere statistic semnificativă a istoricului de infecţie cu *E. vermicularis,* cu creşterea riscului de rinoconjunctivită alergică şi dermatitiă atopică, rezultate ce contrazic studiul efectuat de Schafer şi colab. care raportează o asociere negativă a dermatitei atopice cu antecedentele de infecţie cu *E. vermicularis* la copii de vârstă şcolară din Germania de Est (5). În mod similar, wheezingul a înregistrat o asociere puternică cu istoricul de helmintiază intestinală, aşa după cum o relevă rezultatele înscrise în tabelul I.

În cazul infecţiei curente cu *E. vermicularis* nu am reuşit să evidenţiem o astfel de relaţie, dar Huang şi colab. indică o asociere negativă în ceea ce priveşte asocierea cu rinita alergică şi astmul (4). Cu toate acestea, procentul de copii cu hiperreactivitate bronşică diagnosticată spirometric (7,14%) a fost semnificativ mai mic decât incidenţa declarativă a wheezingului (39,17%).

CONCLUZII

Reactivitatea cutanată la alergeni depinde de intensitatea şi statusul cronic al infecţiei helmintice, infecţia cronică, masivă protejând copilul împotriva atopiei (6,7,8).

Ingestia de antibiotice în primul an de viaţă se asociază semnificativ cu creşterea riscului de wheezing, dermatită atopică şi rinoconjunctivită alergică, substratul fiziopatologic fiind reprezentat de modificarea florei intestinale. Acest fenomen este întreţinut de diagnosticarea eronată a simptomatologiei alergice drept infecţie respiratorie şi administrarea nejustificată de antibiotice. Wheezingul apare frecvent la pacienţii cu reflux gastroesofagian datorită reactivităţii bronşice crescute şi microaspiraţiilor pe care acesta le antrenează (9,10). Contactul cu animalele de companie se asociază negativ cu dermatita atopică şi constituie un factor de protecţie împotriva afecţiunilor atopice. Alţi factori concuratori, alimentarea cu lapte de vacă, expunerea la fumul de ţigară nu au un impact semnificativ asupra afecţiunilor analizate.

NOUTĂŢI

Noi opţiuni terapeutice în cazul infecţiilor produse de *Klebsiella pneumoniae* producătoare de carbapanemaze

Existenţa tulpinilor de *Klebsiella pneumoniae* producătoare de carbapanemaze a fost prima dată raportată în Carolina de Nord iar frecvenţa izolării acestora este în creştere. Polimixina B rămâne unul dintre antibioticile încă active asupra acestor tulpini dar, din păcate, nivelul concentraţiei minime inhibitorii este foarte ridicat lăsând clinicienilor puţine opţiuni terapeutice. În cadrul acestui studiu s-au investigat câteva antibitotice testându-se sinergismul lor antimicrobian atunci cand sunt asociate cu polimixina B împotriva a 12 tulpini de *Klebsiella pneumoniae* producătoare de carbapanemaze (identificarea genelor care codifică acest caracter făcându-se prin *Real Time* PCR). De asemenea valorile concentraţiei minime inhibitorii în acest caz au fost cuprinse în intervalul 16-128 μg/ml. Polimixina B a fost studiată în combinaţie cu cefazolin, ceftriaxona, cefepime, imipenem, gentamicina, tigecyclina, doxycyclina, şi rifampicina. Sinergismul antibacterian a fost observat în cazul combinaţiilor dintre polimixina B şi doxiciclină şi dintre polimixina B şi rifampicină (valoarea concentraţiei minime inhibitorii scăzând de patru ori). Pentru ambele combinaţii efectul sinergic antimicrobian a fost observat la concentraţii ale antibioticelor care pot fi atinse în mod fiziologic.Un efect sinergic mai scăzut a fost observat în cazul asociaţiei dintre tigecilina şi polimixina B, iar în restul cazurilor sinergismul antibacterian nu a putut fi evidenţiat. Astfel, în conformitate cu aceste rezultate, doxiciclina şi rifampicina pot fi asociate polimixinei B în vederea tratării infecţiilor produse de tulpini de Klebsiella pneumoniae producatoare de carbapanemaze, urmând ca viitoarele studii sa stabilească dacă rezultatele testării *in vitro* sunt asociate cu succesul terapeutic obţinut *in vivo* (Elemam A, Rahimian J, Doymaz M. *In vitro* evaluation of antibiotic synergy for polymyxin b-resistant carbapenemase-producing *Klebsiella pneumoniae*. *J Clin Microbiol* 2010 ; 48 : 3558-3562).

ONE-MINUTE SIT-TO-STAND TEST–A USEFUL TESTING TOOL FOR THE PATIENTS WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE (Abstract): Exercise tolerance of patients with chronic obstructive pulmonary disease (COPD) should be carefully assessed in order to gain an optimal quality of life through pulmonary rehabilitation programs. The 1-minute sit-to-stand test (1-min STST) is part of the larger family of sit-to-stand tests which were developed recently as feasible options to evaluate the physical capacity in COPD patients, based either on the time needed to perform a preset number of repetitions or on measuring the number of repetitions performed in a preset period of time. 1-min STST is easy to perform in clinical practice and the results are similar in estimating physical capacity as those generated by other tests, like the 6-minute walk test (6MWT). The 1-min STST performance is predicted by age, sex, smoking status, body mass index, and level of perspiration during physical activity. The results of the test are correlated with the quality of life scores and prognostic indices. The studies to date proved that 1-min STST is an alternative reliable tool to more traditional but also more exhausting exercise capacity tests in COPD patients. **Keywords**: SIT-TO-STAND TEST, CHRONIC OBSTRUCTIVE PULMONARY DISEASE, EXERCISE CAPACITY.

For the chronic obstructive pulmonary disease (COPD) patients the daily physical tasks can be a target sometimes too difficult to achieve. Thus, in order to gain an optimal quality of life for these patients, their exercise tolerance should be carefully assessed, and pulmonary rehabilitation programs should be included in optimal disease management along with smoking cessation (1-4).

In daily practice, exercise tests as the incremental shuttle walk test, endurance shuttle walk test, stair climbing test, 6-min walk test (6MWT), step test or sit-to-stand (chair rise) test (STST) should assess functional capacity, in addition to lung function tests. The gold standard of these usual tests for evaluating exercise tolerance in terms of dyspnea and oxygen desaturation as well as aerobic capacity in terms of walked distance or fatigue is the 6MWT (5).

In 1985, the sit-to-stand test (STST)

was described for the first time (6) and then was associated with increased popularity among researchers mainly due to the simplicity of the movement – standing up from a chair (7). There are several versions of STST available, the main difference being the number of repetitions performed and, as a consequence, the duration of the test. As a result, the mobilized physical resources of the patient and the exercise-induced symptoms and perceived difficulty are variables. The most accepted variant of the STST is the 1-minute sit-to-stand test (1-min STST) that outlasted the variant consisting of 5 repetitions.

MATERIAL AND METHODS

We performed a search of the medical literature, to find out the role and usefulness of 1-min STST in COPD patients. Data sources were represented by several renowned electronic medical databases-MEDLINE, Cochrane Library, Google Scholar and the search terms were SIT-TO-STAND TEST, CHRONIC OBSTRUCTIVE PULMONARY DISEASE, and EXERCISE CAPACITY. We have identified and critically selected relevant research (systematic reviews, meta-analysis, narrative reviews, clinical guidelines, randomized controlled trials and non-randomized but meeting scientific quality criteria) from the last ten years, written in English language, full text available, regarding STST (1-minute and other variants, like 30 seconds or 3-minute) (8, 9).

RESULTS AND DISCUSSION

1. A general view of STS. Different versions of the test

Due to the fact that for COPD patients the two commonly accepted and used exercise capacity tests (6MWT and incremental shuttle walk test) are difficult to use in outpatient settings and primary care due to special requirements needed (time, space and resources) (10), the development of a much simpler and easier to achieve evaluation tool was needed. A movement used in everyday life – the sit-to-stand movement, was the base for the development of a new family of tests by Csuka and McCarty (6). These tests are based either on the time needed to perform a preset number of repetitions (5 repetitions - STST) or on measuring the number of repetitions performed in a preset period of time (1-min STST). Over time, different versions of the STST were used in various populations, to asses lower extremity muscle strength and evaluate the functional capacity of the disabled patients, in order to provide useful information on their independence or disability in daily life (11).

2. Measurements and reference values for 1-min STST

1-min STST requires simple conditions: a chair and a stopwatch. Usually, to perform a 1-min STS test, a trained nurse has to ask the patient to sit down on a chair without armrests, height usually about 46-48 cm, the same chair used for all the patients. The height of the chair should be adapted to the morphology of the patient performing the test. The subject is invited to keep the feet parallel (the legs should not touch the chair) at least as wide apart as the hips and to have the arms hang down loosely, on the hips or crossed on chest (12). The assisted use of the arms is not allowed during the 1-min STST. The patient is asked to fully stand up with the legs straightened entirely (complete knee extension) and then to sit down the chair, which had to be touched by the buttocks.

The nurse asks the patient to complete as many as possible sit-to-stand cycles within 60 seconds at a self-determined speed. Usually, the person who supervises

the test informs the patient when 30 and respectively 15 seconds were left and is counting the number of fully completed STS cycles; not completed or incorrectly performed STS cycles are not counted. There should be a motivation of the patient to perform as many cycles as possible but without any pressure on participants with musculoskeletal or neurological conditions, who felt unable to complete the 1-min STST. The results of a Swiss population-based study (13), which included 6,926 participants which completed the test, have determined the sex- and age-stratified reference values for the 1-min STST for a European adult population, up to the age of 79 years old (tab. I).

TABLE I

Reference values of 1-min STST (adapted from Strassmann *et al.*) (13)

Age group (years)	Number of STS repetitions Men (p 97,5*)	Number of STS repetitions Women (p 97,5')
20-24	72	70
25-29	74	68
30-34	72	68
35-39	72	63
40-44	69	65
45-49	70	63
50-54	67	60
55-59	63	61
60-64	63	55
65-69	60	53
70-74	59	51
75-79	56	43

*97,5 percentile

The 1-min STST performance was predicted by age, sex, smoking status, body mass index, and level of perspiration during physical activity. Usually, there is a small learning effect, thus some researchers are suggesting that, if possible, the test should be performed twice, and the higher scores obtained to be used. However, other studies suggest that the learning effect is not important and reliable results can be obtained with a single performance of the 1-min STST (9).

3. 1-min STST *vs.* other functional tests in COPD patients

Only recently STS tests started to be used in COPD patients and their use increased markedly during the last decade, being also associated with the first studies analyzing the efficiency of STST use in COPD patients (12). These studies were designed to assess the relevance of STST in the evaluation of the functional status of COPD patients when compared with 6MWT. Many studies found significant correlations in terms of functional performance, dyspnea, and quadriceps strength between 6MWT and 1-min STST (6, 14-16). For other parameters, like heart rate, systolic blood pressure, and oxygen saturation, some studies found 1-min STST less stressful than 6MWT. These parameters were significantly modified during 6MWT, a situation not encountered in 1-min STST.

Data published by some researchers (9, 12) indicated that only the 3-min STST is equivalent with 6MWT from the point of hemodynamic stress of the patient during the test but similar results of 6MWT and 1-min STST were recorded when quadriceps strength, end-exercise oxygen consumption, carbon dioxide output, ventilation, breathing frequency, and heart rate were analyzed. These results demonstrated that 1-min STST can be considered a useful tool to assess functional status and lower limb activity in COPD patients, but the different versions of the STST are not equivalent, due to the fact that the length of the exercise is associated with different physiological processes (17).

4. STST in other pulmonary diseases

Radtke *et al.* (18) analyzed the use of 1-min STST in other respiratory diseases. In cystic fibrosis, the 1-min STST was

designed as a cheap, valid and promising alternative to asses muscle function of the patients. Due to the fact that these conclusions were obtained by a study realized on 14 patients with CF, the results must be confirmed by larger studies in different populations.

5. Value of STS in evaluation of the morbidity and prognosis in COPD

Van Gestel *et al.* (19) have confirmed that in patients with COPD, the ability to exert physical effort is correlated with the survival.

Except for the role in the evaluation of the functional status in COPD patients, the 1-min STST test has proved its utility as a tool for survival prognosis in these patients. A study (20) realized on 409 patients, showed that a lower number of rises on 1-min STST test correlates with a higher mortality rate at 2 years. The patients who weren't able to perform more than 12 rises in a 1-min STST have a lower metabolic power, which is associated with a higher risk of mortality. The 1-min STST performance is inversely correlated with the BODE index (21-23), that encompasses four variables: body mass index (BMI), dyspnea, obstruction, and exercise capacity and is proved to be associated with the mortality in COPD at 52 months (23).

Researchers (9, 15, 24) confirmed also that 1-min STST is an effective tool for measuring the efficiency of a pulmonary rehabilitation program; an improvement of 3 rises in 1-min STST is consistent with the benefits of a pulmonary rehabilitation program.

CONCLUSIONS

Our evaluation of the 1-min STST revealed that this test, based on a simple movement, can be realized in almost every clinical setting. Even under the conditions of COPD patients whose walking distance is reduced, this type of requested movement - sit-and-stand, can be performed several times during the day. The necessary equipment is not expensive, and the patients easily understand how to perform correctly the test. Recent studies indicate a good correlation between 1-min STST parameters and other functional tests or prognostic indices. Based on our research of the literature, we concluded that in COPD patients, the 1-min STST elicited a physiological response similar to that of the 6MWT, a more traditional but also more exhausting exercise capacity test in chronic respiratory patients.

2. Institute of Gastroenterology and Hepatology

COLONOSCOPIC SCREENING OF ASYMPTOMATIC FIRST-DEGREE RELATIVES OF COLORECTAL CANCER PATIENTS (Abstract): **Aim**: First-degree relatives of colorectal cancer (CRC) patients are at increased risk for developing colorectal neoplasm, and current guidelines recommend screening colonoscopy in such individuals. The aim of this study was to evaluate the use of colonoscopy as the screening test in asymptomatic first-degree relatives of CRC patients. **Material and method**: Colonoscopy was performed in 102 asymptomatic individuals who had at least one first-degree relatives with CRC. Subjects included in the screening program were aged between 36 and 72 years, and majority came from two counties (Suceava, Iaşi) located in north-eastern Romania. **Results**: Thirty colorectal lesions were found in 17 individuals: two (6.6%) had adenocarcinomas, and remaining 15 patients had 28 polypoid lesions: 14 (46.6%) adenomas, 5 (16.6%) tubulovillous adenomas, 3 (10%) adenomas with high grade dysplasia and 6 (20%) had hyperplasic polyps. **Conclusion**: Colonoscopy is a useful, feasible and safety initial screening tool for first-degree relatives of patients with CRC. **Key words**: COLORECTAL CANCER, COLONOSCOPY, FIRST-DEGREE RELATIVE, SCREENING

Colorectal cancer (CRC) is the second leading cause of death from malignancies in most western developed countries (1). In Romania, the incidence of CRC has significantly increased over the last two decades, and now it has the tendency to exceed the gastric cancer, which is still the most frequent malignancy encountered in our country (2).

The goal of cancer screening is to reduce mortality through a reduction in incidence of advanced disease. CRC screening can achieve this goal through the detection of early-stage of adenocarcinomas and the detection and removal of adenomatous polyps (3). Recent trends in CRC incidence and mortality reveal declining rates, which have been attributed to the effect of screening and early detection and prevention through polypectomy (4,5).

Colonoscopy performed by experienced endoscopists is regarded as "gold standard" method for CRC screening; it seems to outperform fecal occult blood test (FOBT) and flexible sigmoidoscopy in the detection of cancer and advanced neoplasia (5).

First-degree relatives of CRC patients are at increased risk for developing colorectal neoplasm, and current guidelines recommend screening colonoscopy in such individuals (6,7,8).

The aim of this study was to evaluate the use of colonoscopy as the screening test in

TABLE I
Characteristics of the screened group

Lesions	Number	%
Adenocarcinoma	2	6,6
Adenomas	14	46,6
Tubulovillous adenomas	5	16,6
Adenoma with high-grade dysplasia	3	10
Hyperplasic polyps	6	20

asymptomatic first-degree relatives of CRC patients.

MATERIAL AND METHODS

In January 2006 we set up a colonoscopy screening program of first-degree relatives of common ("sporadic") CRC patients (those cancers not associated with familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, or inflammatory bowel disease). The potential screenees were invited to an interview and after detailed information about an increased risk for the development of CRC for first-degree relatives, a colonoscopy was suggested. All the subjects interviewed were asymptomatic, and those who agreed for screening received colonoscopic examination. All colonoscopies were performed by experienced endoscopists at Iaşi Institute of Gastroenterology and Hepatology and Suceava County Hospital. The majority of screened subjects came from north-eastern region of Romania (Iaşi and Suceava counties).

RESULTS

Out of 216 subjects interviewed, 114 (52.7%) refused colonoscopy or any other type of screening test, and 102 (47.3%) subjects agreed to have a colonoscopy examination. The characteristics of screenees are presented in table I.

The endoscopic findings are shown in Table II. Overall, there were 30 lesions in 17 patients: 2 (6,6%) adenocarcinoma (one patient with Dukes A stage, the other with Dukes B), and 28 polypoid lesions in 15 patients (14 adenomas, 5 tubulovillous adenomas, 3 adenomas with high grade dysplasia and 6 hyperplasic polyps).

DISCUSSION

Familial risk of CRC is well-known and current guidelines recommend screening colonoscopy in first-degree relatives of patients with CRC (6,7,8). Several studies investigated the effectiveness of colonoscopy screening in close relatives of patients with common ("sporadic") CRC (those cancers not associated with familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, or inflammatory bowel disease) (9,10,11,12, 13,14,15,16,17,18).

Colonoscopy performed by experienced

TABLE II
Results of histological examinations of the colonoscopic findings

No. of participants	102
Sex (M/F)	57/45
Mean age (range)	52±9.6 yrs (36-72 yrs)
Origin of participants	
Iaşi county	51 (50%)
Suceava county	32 (31,3%)
Others	19 (18,6%)
Relative affected by CRC	
Parents	86 (84,3%)
Siblings	16 (15,6%)

endoscopists is regarded as "gold standard" method for CRC screening; although is invasive and operator dependent, colonoscopy has the highest sensitivity among current methods, examines the entire colon, is cost-effective, and offers diagnosis and therapeutic opportunity in a single-session and the longest interval protection. Therefore, we adopted colonoscopy as a screening procedure for CRC, and the compliance was acceptable (47.3%). We did not routinely use sedation, and the cecum was intubated in 92.15% of colonoscopies. Therefore were no complications during colonoscopic examinations.

We found 30 lesions in 17 patients, a figure which is certainly higher than found in the general population aged over 50 years in our region. Our study confirmed the results of the other studies (9,10,12,13,15, 16,17). Thus, Baker et al. (15) reported 166 lesions (27% neoplastic) in 85 (42%) out of 201 asymptomatic patients who underwent colonoscopy based solely on a family history of CRC. Guillem et al. (12) prospectively colonoscoped 181 asymptomatic first-degree relatives of CRC patients and 83 asymptomatic controls, and found an increased prevalence of adenomas in first group. Pezzoli et al. (10) reported the results of a 5-years CRC screening program in asymptomatic subjects at increased risk and found colonoscopy-based screening feasible, effective and well accepted. Ruthotto et al. (9) investigated the compliance for colonoscopy in first-degree relatives of patients with CRC and found that less than 40% of them participate in colonoscopy screening for CRC; the authors suggested that better information of CRC patients about the potential risk for their relatives will increase participation in screening colonoscopy in their first-degree relatives. Wu et al. (17) found a high acceptability and safety of colonoscopy in screening persons with family history of CRC, and suggested the use of colonoscopy as an initial screening procedure. Similar results were reported by Syrigos et al, and other studies (16,18).

CONCLUSION

Our study shows that screening colonoscopy in first-degree relatives of patients with CRC is feasible, safe, and generally well accepted. First-degree relatives of CRC patients have a higher percentage of neoplasms than average-risk population from our region. The compliance rate in screening colonoscopy was acceptable and may increased by direct physician-patient contact.

NOUTĂŢI

NIVELURILE SERICE ALE VITAMINELOR B SUNT INVERS PROPORŢIONALE CU RISCUL DE CANCER BRONHO-PULMONAR

Studiul european prospectiv de tip caz-martor EPIC (European Prospective Investigation into Cancer and Nutrition), desfăşurat între 1992 şi 2000, a cuprins 519978 subiecţi din 10 ţări europene, din care 385747 erau donatori de sânge. La aceştia au fost puse în evidenţă 899 cazuri de cancer bronho-pulmonar (CBP), ce au fost comparate cu 1770 de cazuri martor, luând în considerare data naşterii, sexul, ţara de origine şi momentul prelevării de sânge. Au fost dozate vitaminele B2, B6, B9 (folaţi) şi B12 ; metionina, homocisteina şi cotinina. După considerarea tabagismului cronic drept un factor potenţial confuzional, compararea între cele două grupuri a arătat că riscul de CBP a fost foarte scăzut în următoarele cazuri : nivel crescut al vitaminei B6, cu odds ratio (OR) – 0,44, $p < 0,000001$; nivel crescut de metionină (OR – 0,52, $p < 0,000001$), ambele tendinţe fiind independente de existenţa tabagismului sau de durata de supraveghere. Riscul de CBP a fost scăzut şi în cazul creşterii folaţilor (OR 0,68, $p = 0,001$) doar la fumători. Acest studiu caz- martor pledează în favoarea unei asocieri inverse între nivelul seric crescut al Vitaminei B6 şi al metioninei şi riscul de cancer bronho-pulmonar. O ipoteză seducătoare pentru eventuale aplicaţii terapeutice (Johansson M et al. Serum B vitamin levels and risk of lung cancer. *JAMA* 2010, 303 : 2377-2385).

PSYCHIATRIC SYMPTOMS IN A PATIENT WITH VON RECKLINGHAUSEN DISEASE. CASE REPORT (Abstract) Neurofibromatosis represents a group of three diseases characterized by tumors of the nervous system. Of these three diseases type I neurofibromatosis (von Recklinghausen disease) is probably the best-known form and it is one of the most common genetic diseases. The clinical manifestations of the disease differ significantly from patient to patient, from the monosymptomatic to the plurisystemic form, and so does diseas e severity. We report the case of a 44-year-old male patient diagnosed with type I neurofibromatosis, his brother and father being also diagnosed with this disease, who during the di s-ease course had many hospitalizations for a depressive syndrome and suicidal ideation. Although the disease course is favorable in most patients, there are numerous complications and a negative impact on the quality of life. **Keywords**: NEUROFIBROMATOSIS TYPE I, DEPRESSION, QUALITY OF LIFE

Von Recklinghausen neurofibromatosis (type I neurofibromatosis) is a chronic progressive inherited disease with an autosomal dominant pattern of inheritance. The disease affects about 1 in 3000 individuals and is mainly characterized by *"café au lait"* spots, neurofibromas and optic glioma (1, 2). The phenotypic expression of type I neurofibromatosis (NF1) is quite variable, with some patients meeting only the minimum criteria necessary for diagnosis, whereas other patients are severely affected by cutaneous symptoms or other manifestation of this disease. NF1 gene has the potential for multiple system involvement and there is often an increase in the number of neurofibromas during puberty, at the time when young people are mostly concerned about their body image (3). A person`s physical appearance, along with his/her sexual identity represent the personal characteristic that are most obvious and accessible to others in social interactions. Generally, empirical research unequivocally documents that greater physical attractiveness is favorable for a person and lesser physical attractiveness is unfavorable. Society is often prejudicing against those with an atypical facial appearance or a disabil- ity. Thus, a person with a facial disfigure- ment may experience severe social rejec- tion (4, 5). Many patients described re-

striction in social contacts and lifestyle changes as they tried to hide peripheral neurofibromas. They are concealing the lumps in order to avoid explaining the condition to other people (6).

There are numerous reports about physical aspects of neurofibromatosis, but information about psychological features of these patients are rare and the reported findings are often based on highly selected groups of patients, sometimes not assessed in a systematic manner. Thus, psychiatric and developmental problems arise in patients with neurofibromatosis, when they are compared with other chronic neurological patients (7). Concomitant occurrence of neurofibromatosis and autism spectrum disorder has also been described in several reports (8, 9). Other studies assessing the psychiatric and social aspects of neurofibromatosis in a carefully defined population showed that the most commonly associated psychiatric conditions were depressive syndrome, anxiety state with vegetative dysfunctions and organic brain syndrome (10, 11, 12). In addition, the data also indicated an excess of occupational disability, unemployment or employment in a position characterized as not requiring special skills.

CASE REPORT

The patient I.F., a 44-year-old male is in the database of the "Socola" Institute of Psychiatry Iasi since 2005. But he was known with depressive symptoms since 2002 and he was treated like an outpatient. The last presentation at the hospital, in January 2018, was for an acute exacerbation of depressive symptoms with moderate depressive mood, psychomotor inhibition, anxiety, mixed insomnia, psycho-emotional lability with frequent crying, bradylalia, bradyphemia, depressive ideation, feelings of worthlessness, reduced self-esteem, hypobulia with social isolation and difficulties to integrate and function in social and family environment. During the current hospital stay (January 15-January 23, 2018) the psychological evaluation revealed astheno-dysthymic state with symptoms of anxiety in a psychosomatic context and emotional lability. The Hamilton Scale for Depression score was 18 points (13, 14). The global assessment functioning scale (GAF) score was 30 points (13). Woodworth-Mathews questionnaire: emotivity = 280, psychasthenia = 240, depression = 280, irritability = 212 (15). The questionnaire for the determination of accentuated personalities: emotivity = 87.5%, anxiety = 87.5% (16).

Also, the patient was diagnosed with several somatic conditions which influenced the current psychiatric symptoms: Recklinghausen disease (neurofibromatosis type I), elephantiasis of the left leg (Virchow neurofibromatosis), hepatic hemangioma, hypercholesterolemia and a minor traumatic head injury, without any immediate or tardive consequences. Physical examination revealed multiple growths all over his body, superficial and deep, of soft consistency, and multiple *"café au lait"* spots on the whole body, but especially at the posterior part of the thorax (fig.1). The patient also presented with left leg and ankle increased in volume suggestive of elephantiasis and venous dilatation in the left leg (fig. 2). We noticed discrete distal trophic changes in both lower limbs and pain at the Arnold points at distal compression (17). Neurological examination revealed active movements in normal ranges, deep tendon reflexes were symmetric, bilateral, normal coordination, and no patho-

logical findings at cranial nerve examination.

Fig. 1. Multiple growths on the skin with a soft consistency and multiple *"café au lait"* spots

Fig.2. Left leg increased in volume, appearance of elephantiasis

Electroencephalogram revealed a series of polymorphic theta waves (6 Hz, 20-30 microV) in the frontotemporal derivations that persisted when the eyes were opened. Basic tracing had a dominant alpha rhythm (11 Hz, 70-90 microV) especially at tempo-ro-parieto-occipital level bilaterally. Attenuation of pupillary reaction to light was normal. Hyperpnoea did not influence the EEG tracing.

The native computed tomography (CT) of the brain revealed: mild supratentorial cerebral atrophy, consistent with patient age. Ventricular system is slightly dilated and symmetrical. A small hypodense area corticalized at left frontopolar level (fig. 3). Numerous small inclusions of adipocyte density, thinning of the cerebral fissure as well as of the superior sagittal sinus and right sinus.

There is an area with the density of the cerebrospinal fluid, without walls, of 21/15/16 mm, probably an arachnoid cyst.

Also, frontal left sinus agenesis and right frontal sinus hypoplasia are observed; numerous oval tumors located bilaterally at occipital level and posterior cervical level, the largest of them of 10/9/16 mm, being located right posterolateral (fig. 4 a, b). All these images observed on the brain scan can have clinical consequences, regarding the future complications or the risk to develop a brain tumor, but the physician did not considered that a contrast-enhanced brain scan is necessary, at this moment of the evolution of the disease.

Fig. 3. Small sequel hypodense area corticalized at left frontopolar level

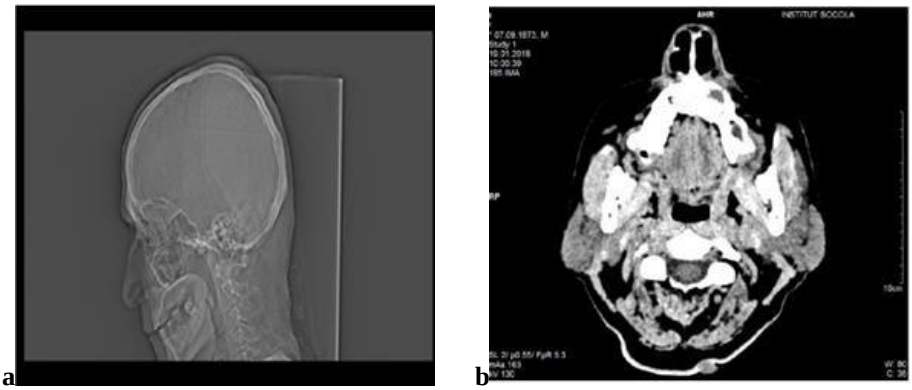

Fig. 4. a. Side image-subsegmental oval tumors located posterior cervical and bilateral occipital; b. Cross section-subcutaneous occipital formation located occipital subcutaneous.

Family history - both father and one brother were diagnosed with the same disease; father died in 2002 from a stroke, his brother was diagnosed with a brain tumor, already surgically removed.

History of the disorder

The onset of the psychiatric disorder was in 2002 after the death of his father, but in 2005 he was admitted to hospital for the first time due to suicidal thoughts. At that time, the symptoms were characterized by suicidal thoughts, marked psychomotor inhibition, mixed insomnia, feelings of guilt. Psychological assessment revealed severe depressive configuration in a person with avoidant personality with self-aggressive manifestations and a major suicidal risk. The treatment initiated at that moment consisted in antidepressant Paroxetinum 40 mg/day, benzodiazepine Diazepam 10 mg/day, sleep inducer Zolpidem 10 mg/day, cerebral trophic and vitamins group B. After his discharge from the hospital, the antidepressant treatment was continued in the outpatient unit; the symptoms remitted, but there was a dysthymic deficit explained by the fact that the patient only partially complied with the treatment.

During disease progression some complications were recorded, including a surgical intervention for a perianal abscess and a neurological symptom (vertigo) accounting for the exacerbation of the depressive symptoms which required a new hospitalization at the psychiatric department of the Iasi Military Hospital. Thus, at that hospitalization, the diagnosis of recurrent depressive disorder was established because the patient had more than two episodes of severe depression, without any manic or hypomanic episodes. The psychiatrist restarted the treatment with antidepressant medication Paroxetinum. His last hospital admission was in 2018 to the "Socola" Institute of Psychiatry Iasi caused to an exacerbation of the depressive symptoms and also because he didn't took any antidepressive medication for almost two weeks. Thus, we confirmed the diagnostic of recurrent depressive disorder.

In the case of a typical depressive episode, irrespective of its mild, moderate or severe intensity, depressive mood, lack of interest or pleasure, decreased energy, which causes increased fatigue and decreased activity are usually found. Marked tiredness after only slight physical effort is

also common. Other common symptoms are: (a) poor concentration and reduced attention span; (b) low self-esteem and self-confidence; (c) ideas of guilt and unworthiness (even in a mild intensity episode); (d) bleak and pessimistic views of the future; (e) thoughts or acts of self-harm or suicidal ideation; (f) disturbed sleep; (g) diminished appetite.

The positive diagnosis of "recurrent depressive disorder" was according to the criteria of International Statistical Classification of Diseases and Related Health Problems (ICD) 10th revised version and these are (18): the criteria for recurrent depressive disorder should be met; the current episode should meet the criteria for depressive episode, moderate severity and at least two episodes that should have lasted a minimum of two weeks and should have been separated by several months without significant mood disturbance. The disorder is characterized by repeated episodes of depression (mild, moderate or severe), without any history of independent episodes of mood elevation and overactivity that meet the criteria for mania.

The patient was unmarried, had no children, graduated ten classes, worked for 15 years, but had been medically retired for the past three years and lived with his family. He retained the ability to organize and plan spending and income, self-care and home care, but had a small group of friends. Currently, he is under antidepressant treatment with Tianeptine 12.5 mgx3/day and Lorazepam 1.0 mg/day for anxiety symptoms, he is compliant to treatment and come regularly to follow-up visits.

An important role in the therapeutic management of the case has been the use of some psychotherapeutic measures besides the pharmacological ones. Thus, psychoeducation aimed at informing the patient and his family about neurofibromatosis, a chronic, disabling illness. Information received by the patient from people around or from the internet was sometimes inappropriate, overwhelming, given the fact that the risk of many complications is exhaustively presented to him (19). Also, the frequent use of the term tumor, even if the majority of the diagnosed tumors are benign, has a negative connotation regarding the perception of the disease by the patient. That is why it has been specifically discussed how the patient assesses the risk of tumor malignancy but explains it in the context of general risk in the population.

By presenting the patient, but also his family to the therapist, the symptomatology of the disease and its possible later complications can be controlled, and the patient can create ways of coping for the situations in which anxiety occurs and they anticipate the unpredictability of the evolution of the disease.

Another important step in patient therapy was the use of cognitive psychotherapy techniques, considering the differences in the responses of patients to the diagnosis of chronic disease. Thus, a focused, structured, short-term psychotherapy, aimed at facilitating problem solving and restructuring dysfunctional thoughts and behaviors, was envisaged. This therapy also targeted depressive symptomatology, adopting and learning active measures to coping symptoms, and establishing an appropriate collaborative relationship with the therapeutic team.

The patient's thoughts related to his diagnosis are "nothing can be good any- more"; if someone has a chronic illness that supports depressive symptoms with suicid- al ruminations there is an important risk of suicidal behavior; also, depression can be

emphasized by avoiding various daily activities. In addition to cognitive techniques, behavioral strategies have been aimed at reducing factors that maintain and exacerbate both depressive-anxious and physical symptoms. Each meeting with the patient, which was initially weekly, and then two weeks, but later for a monthly therapy session to date, had a well-established working agenda. Of course, this agenda has been modified according to the patient's new needs, specific to each meeting, but also to our need to cover certain points of the meeting. Thus, the patient made journals in the form of homework that were discussed, by focusing on dispositional, behavioral changes, as well as thoughts with negative, intrusive or ruminative connotations correlated with the diagnosis of chronic or suicide-related disorders.

Thus, the patient noted the thoughts and emotions determined by the fact that he was diagnosed with a chronic, genetic transmission disorder requiring multiple treatments and periodic clinical assessments, with many risks and complications for the future. It also quantified how different somatic complications had an impact on daily functionality and various activities as a result of pain or other physical symptoms and how often it needed reassurances regarding its subsequent family evolution or different medical professionals. The fact that the patient has a genetic disease with uncertain evolution for the future makes him depressed, anxious, so our role has been to improve our patient's own coping mechanisms, the long-term self-management of this disease. Bearing in mind the lower compliance of the patient to drug therapy, there have been special sessions dedicated to this aspect of the therapeutic plan. In this regard, he has been taught to keep a journal about the times when he is taking his medication, as well as those in whom he has depressive and anxious symptoms, and to see if there is a correlation or not between these periods. Thus, it was intended to increase therapeutic long-term compliance as we found that discontinuation of medication was a trigger in worsening of psychiatric symptomatology.

DISCUSSION

Neurofibromatosis, a chronic progressive genetic disease, has a dominant autosomal transmission and its penetrance is almost complete by five years of age. Our patient was diagnosed with the disease from birth. The disease is characterized by benign tumors in any organ, especially on skin, but they can also be present in the nervous system, eyes or bone system. The number and size of these tumors increase in time and spread out over the whole body. The presence of brown, *"cafe au lait"* spots and nervous malformations can also be encountered. The treatment is being symptomatic, and it is represented by surgical removal of the tumors.

In the patients with this disease, psychiatric disorders can be more frequent than in general population and include dysthymia, depressive mood, anxiety, and personality disorders. In the here-reported case, the prognosis of the psychiatric disorder is influenced by the future course of the neurofibromatosis complications and especially by the cerebral complications.

The psychiatric symptoms and their impact to functioning were evaluated using some psychometric scales. The Hamilton Scale for Depression score was 18 points, means a moderate depression. This scale is used to determine the severity of depres- sion and can be also used in psychophar-

macological research to evaluate compliance and response to treatment. It was published in 1960, revised in 1967 by Max Hamilton and is one of the first instruments to evaluate the severity of depressive symptoms. It is a 17-item scale which measures the intensity of symptoms specif- ic to a depressive syndrome according to DSM IV (Diagnostic and Statistical Manual of Mental Disorders 4th edition) criteria for diagnosis. It is quite sensitive to changes in symptoms during an antidepressant treat- ment (13, 14).

The global assessment functioning scale (GAF) score was 30 points, means his inability to function in almost all areas of life, like occupational, familial or social functioning caused to the severity of the psychiatric symptoms. The global assessment functioning (GAF) scale evaluates the correlation between social functioning, adaptive incapacity and working capacity.

The dysfunctions can be primary, like in the case of a disease, lesions or brain trauma, or secondary, like in a systemic disease which affects the brain and other organs (13).

Woodworth-Mathews questionnaire: emotivity = 280, psychasthenia = 240, depression = 280, irritability = 212. The *Woodworth Mathews Questionnaire* contains 76 questions that highlight the psychopathological tendencies of personality. The Romanian standard of multifactorial profile for psychopathological tendencies reveals a marked risk of inadequacy for scores between 180-260 and a pathological risk for scores between 260 and 360 (15).

The questionnaire for the determination of accentuated personalities: emotivity = 87.5%, anxiety = 87.5%. This questionnaire was developed by H. Schmiescheck for the identification of accentuated personality traits according to the theory of the neuropsychiatrist Karl Leonhard (16).

The short-term prognosis of the depressive syndrome is favorable given that adequate antidepressant therapy has been instituted, the patient is compliant with treatment, the intensity of depression is moderate, and the patient has good social and family insertion. Reduced quality of life is determined by the motor deficit - elephantiasis and disfigurement is determining a tendency to social isolation.

Medium and long-term prognosis is worsened by the probability to develop an expansive intracranial process, suggested by the changes observed on CT brain scan. Also, a family history of cerebral tumors additionally increases this risk. If an intracranial expansive process is diagnosed, secondary cognitive dysfunction can be developed even if the tumor can be resolved surgically or not. Additionally, there is a risk of intracranial hypertension and we recommended the patient to be evaluated by a neurosurgeon in order to create a multidisciplinary team together with the general practitioner, neurologist and psychologist to prevent any other severe complications. Moreover, the symptoms of anxiety or depression developed in an organic context may have negative consequences in terms of the therapeutic response to psychotropic medication comparing with a case without any somatic issues. Considering the patient's history of suicidal behavior, he will have suicidal ideation in the future, suicidal risk being one of the most severe complications.

Risk of progredient development of new tumors will increase the risk of affecting major peripheral nerves with secondary functional impotence, limiting activities with negative consequences on psychiatric

symptoms and especially on the depressive syndrome. Antidepressant treatment will be necessary for a long period of time with regular follow-up and regular psychiatric visits to increase the quality of life of the patient.

CONCLUSIONS

In this case, a multidisciplinary team will be essential for improving the prognosis of this patient. Society is often prejudicing against those with lesser physical attractiveness or atypical facial appearance or handicap. It is important for the patient to be encouraged to have an insertion in his socio-familial environment, to keep the capacity of organizing and planning of income and expenses, the capacity of self-care and the upkeep of the house. Any psychological difficulties regarding self-esteem or feelings of rejection from others must be discussed and the patient can learn how to accept and deal with the problems related to the physical aspects of the dis- ease as well as the somatic and psychiatric ones (20).

The particularity of this case is due to the relatively early onset of depressive symptomatology, which occurred in a reactive-situational context and which was aggravated by the pre-existing chronic disease, neurofibromatosis. Thus, psychological counseling and periodic psychiatric evaluation of these patients, who are diagnosed with chronic hereditary diseases, such as neurofibromatosis, should diagnose and treat, as soon as possible, the psychiatric symptomatology that can be associated.

NEWS

MAGNETIC RESONANCE SPECTROSCOPY – CLINICAL APPLICATIONS

The basic principle of magnetic resonance spectroscopy is that the distribution of electrons around an atom cause nuclei in different molecules to experience a slightly different magne t-ic field. This results in slightly different resonant frequencies, which in turn return a slightly different signal. Magnetic resonance spectra can be acquired from any "active" nucleus: protons, carbon-13 and phosphorus-31 and. In clinical practice only proton spectra (which enable the resolution of metabolite profiles in vivo) are encountered. Magnetic resonance spe c-troscopy (MRS) is performed with many pulse sequences, for example spin echo sequences, can measure the peaks of N-acetyl aspartate, creatine, choline, lactate in different tissues and has various clinical applications. Can help increase our ability to predict glioma's grade: as the grade increases, N-acetyl aspartate (NAA) and creatine decrease and choline, lipids and lactate increase. We can differentiate radiation change and tumor recurrence: in recurrent tumor choline will be elevated, whereas in radiation change, NAA, choline and creatine will all be low. When brain infarction takes place lactate will increase, then lipids are released, and peaks appear. Within bacterial abscess cavities, lactate is elevated.

THE INCIDENCE OF ADVERSE EFFECTS ON ANTIEPILEPTIC MEDICATION IN CHILDREN DIAGNOSED WITH EPILEPSY

THE INCIDENCE OF ADVERSE EFFECTS ON ANTIEPILEPTIC MEDICATION IN CHILDREN DIAGNOSED WITH EPILEPSY (Abstract): The treatment of epilepsy is complex and its purpose being to achieve the best possible control of seizures with minimal side effects. The presence of side effects of antiepileptic drugs is one of the major problems of antiepileptic therapy. The aim of the study was to evaluate the incidence of side effects of antiepileptic drugs in children diagnosed with different types of epilepsy. **Material and methods:** The authors followed 247 patients aged between 0 and 17 years old, diagnosed with epilepsy between 01.01.2010 - 01.12.2018. The study analyzed retrospectively the evolution of the seizures under treatment and the presence of the side effects of antiepileptic drugs. The Composite Index of Impairments was used in order to properly evaluate the problems caused by the medicine used. **Results:** From the study group 47.77% of the patients reported side effects, more commonly in children receiving polytherapy (88.46%). In 96.61% of children, the severity of the side effects was low/medium and 4 patients (3.39%), adverse reactions were severe, the score at Composite Index of Impairments being ≥50. The most frequent adverse reactions were represented by behavioral changes, sleepiness, gastrointestinal disorders. **Conclusions:** Patients who received antiepileptic therapy in polytherapy had more frequent side effects than those who undergone monotherapy. The presence of adverse events has an undeniable negative effect on the quality of life of children diagnosed with epilepsy. **Keywords:** ANTIEPILEPTIC DRUGS, ADVERSE EFFECTS, CHILDREN.

The treatment of epilepsy is complex and the improvement of the diagnostic methods as well as the discovery of new antiepileptic drugs have led to the development of therapeutic possibilities of epileptic seizures in the child. Antiepileptic therapy is symptomatic, its purpose being to achieve the best possible control of seizures with minimal side effects. The presence of adverse reactions is one of the major problems of antiepileptic therapy. They alter the clinical picture, adding its own symptoms which negatively affect the quality of life of the patient. Complete seizure control is important for most patients suffering from epilepsy; they are generally

accepting the adverse effects of medication and continue antiepileptic treatment.

The aim of the study was to evaluate the incidence of side effects of antiepileptic medication in children diagnosed with different types of epilepsy given the fact that most studies in pediatric patients with epilepsy are focused on the clinical effectiveness of antiepileptic medication.

MATERIAL AND METHODS

In our study we followed children aged between 0 and 17 years old, diagnosed with epilepsy in the Pediatric Neurology Department of the "Sf. Maria" Emergency Clinic Hospital for Children, Iasi, Romania between 01.01.2010-01.12.2018. The study analyzed retrospectively the evolution of the seizures under treatment and the presence of the side effects of antiepileptic drugs. Patients were included in study had two or more epileptic seizures diagnosed by a doctor (family doctor or neuropediatrician). Repeated seizures (two or more) within 24 hours were considered to be a single seizure. Children who had only simple febrile seizures, without presenting any other seizures without fever, were not included in the study. Those with febrile epileptic status were considered to have epilepsy only if they also had seizures without fever. The diagnosis of epilepsy was based on electro-clinical data. As for the children who displayed several types of seizures, it was decided which type was the most significant from the clinical perspective. However, information about the other forms of seizures was recorded as well.

Epileptic seizures and syndromes have been classified according to the International League Against Epilepsy Classification of 2010 (1). The study group included 247 children, out of which 106 girls and 142 boys. 102 (41.29%) were diagnosed with presumed genetic epilepsy, 13 (5.27%) with unknown cause of epilepsy and 132 (53.44%) with structural-metabolic epilepsy. Of the children studied, 89 (36.03%) presented partial seizures, 152 (61.53%) generalized seizures, and 6 (2.44%) other types of seizures.

169 (68.42%) of the patients received monotherapy and 78 (31.58%) of the patients received polytherapy. All antiepileptic drugs were prescribed in therapeutic doses. Sodium valproate (VPA), Lamotrigine (LTG), Topiramate (TPM), Oxcarbazepine (OXC), Levetiracetam (LEV) and Carbamazepine (CBZ) were used in both monotherapy and polytherapy. Benzodiazepines (BZD), Phenobarbital (PB), Ethosuximide (ETX), Stiripentol were used only in association.

The Composite Index of Impairments was used in order to properly evaluate the problems caused by the medicine used - table I, which contains 3 subscales, Seizure Activity Index which analyzes the type and frequency of the crises, The Neurotoxicity Rating Scale (neurotoxicity index) which assesses the severity of the secondary neurological effects and the Systemic Toxicity Rating, which assesses the severity of systemic side effects of antiepileptic drugs (2).

The score for each symptom ranges from 0 to 50. The 0 score indicates complete seizure control and the absence of side effects, while a score of 50 or >50 stands for low seizure control and the presence of side effects which required the modification of the therapeutic regimen (tab. II).

TABLE I

The range of the toxicity score for each symptom used in CII

Effect	Score	Effect	Score
Neurotoxicity		*Systemic toxicity*	
◆ diplopia	15-30	◆ oral and gingival impairments	3-20
◆ nystagmus	5-10	◆ gastrointestinal impairments	3-50
◆ dysarthria	5-30	◆ hematopoiesis disorders	50
◆ ataxia	5-50	◆ dermatological impairments	20-50
◆ tremor	10-50	◆ renal impairments	50
◆ emotional instability and mood disorders	5-50	◆ liver impairments	25-50
◆ cognitive and behavior disorders	5-50	◆ weight gain or weight loss	3-20
◆ dizziness	3-50	◆ hair loss	5-50
◆ headache	3-50		
◆ sedation	5-50		

TABLE II

Side effects of antiepileptic drugs correlated with the values of the CII score

CII	Neurological and/ or systemic side effects	Epileptic seizures control
0	0	good
1-10	easy	acceptable
11-49	moderate	acceptable
≥ 50	severe	absent

RESULTS

In our study, 129 (52.23%) of patients did not report any adverse effects of antiepileptic drugs, the score measured by the Composite Index of Impairments being 0. 118 (47.77%) of patients reported adverse effects, out of which 67 (56.77%) of patients only one adverse effect and 51 (43.23%) of patients at least two adverse reactions.

Side effects were more commonly reported in children receiving antiepileptic treatment in polytherapy (88.46%) compared to those receiving monotherapy (28.99%).

In 114 (96.61%) of children, the severity of the side effects was low/medium, in these cases the score at Composite Index of Impairments ranging between 1-49. In 4 patients (3.39%), adverse reactions were severe (2 cases of Steven Johnson syndrome in combination with Lamotrigine, one case of acute renal failure at the initiation of Topiramate treatment, one case of toxic hepatitis in combination with Stiripentol), this time the score at Composite Index of Impairments being ≥50.

Antiepileptic medication was discontinued and considered responsible for adverse reactions in children with skin rash following the administration of antiepileptic drugs (Sodium Valproate, Phenobarbital, Levetiracetam) and in all those with severe side effects. In other 20/118 cases, the antiepileptic drugs dose was reduced in case of side effects.

The most frequent adverse reactions were represented by behavioral changes, sleepiness, gastrointestinal disorders (tab. III).

TABLE III

The distribution of adverse effects associated with antiepileptic medication

Adverse effects	VPA	CBZ	LTG	TPM	LEV	OXC	PB	ETX	Stiripentol	BZD
Neurotoxicity										
diplopia		3								
nystagmus						1				
dysarthria										
ataxia					1	1				
tremor	3		3							
emotional instability and mood disorders		2					3			
cognitive and behavior disorders	6	8	1	4	3		5			
dizziness		2				2	3			6
headache			5			3	2			3
sedation	3	5		3	1	4	4			5
Systemic toxicity										
oral and gingival impairments	2	3								
gastrointestinal impairments	8	10	4	4	3	6		2		
hematopoiesis disorders										
dermatological impairments	5	2	2		1		5			
renal impairments				1						
liver impairments	4	5							1	
weight gain or weight loss	8	7		4						
hair loss	6		1							

DISCUSSION

According to The Food and Drug Administration's definition, the adverse effects are regarded as "any adverse event associated with the use of a drug in humans, even if it is not considered to be associated with the drug" (3). From the classifications of adverse effects, the most useful one is the idiosyncratic or dose-related classification because it manages to identify the drug as the cause of the adverse effect; if there is a connection with its dose, it results that a dose reduction will cause the reduction/disappearance of the adverse reaction (4). At the same time, classification in connection with the organ that may be affected is useful in the clinical and paraclinical monitoring of the specific organ which must be carefully monitored during treatment (4, 5).

The presence of adverse effects in antiepileptic drugs is an important problem of children diagnosed with epilepsy who require chronic treatment.

In the study we conducted, 47.77% of evaluated patients had adverse reactions: 56.77% reported a single adverse event, while 43.23% at least two side effects.

The occurrence of side effects varied with the type of antiepileptic drugs used. For example, in patients who received VPA, gastric discomfort and weight gain were the most usual problems caused by medication; in the case of LTG treatment, headache and gastrointestinal disorders; in patients treated with TPM, anorexia and weight loss, emotional lability, difficulty concentrating. In the case of antiepileptic medications, the presence of the side effects depended on the way the medication was introduced, thus the rapid increase of the dose of LTG favored their occurrence.

Depending on the therapeutic scheme used, there were differences regarding the occurrence of adverse effects, more frequent in patients who received polytherapy (88.46% of patients), but there was no distinction regarding the intensity of issues caused by medication. Sedation and cognitive disorders were two of the most usual neurological side effects in children with polytherapy.

This data are similar to that which was reported in the literature. In a prospective study which included 180 children with epilepsy, 135 of whom received monotherapy, and 45 with polytherapy, Anderson and co-workers (2015) reported the presence of adverse effects in approximately 1/3 of the patients. In 61% of the cases, the adverse reactions were average, in 3 cases being severe (2 cases with Steven Johnson syndrome and one case with respiratory arrest). The most common adverse events reported were behavioral disorders (12%), sleepiness and sleep problems (10%) (6).

Also, Peruca *et al*. (2009) examined the existence of at least one side effect in 88% of the patients followed and at least two adverse reactions in 82% (7). The most prevailing adverse events observed were fatigue (63.3%), memory disorders (58.3%), difficulty concentrating (44.4%), nervousness or agitation (43.2%), headache (42.7%), drowsiness (41.1%).

Jayalekshmi *et al*. (2016) reported the presence of side effects in 56 cases, of which 42.85% were represented by manifestations due to central nervous system damage. These observations were made in a study in which 180 patients with epilepsy (8).

In our own study, adverse effects occurred most frequently at the initiation of treatment. In no patient was it observed the increase of the risk of occurrence of new secondary events, simultaneously with the increase of the duration of treatment. There were no specific side effects in connection with a certain age.

CONCLUSIONS

Antiepileptic medication is generally well-tolerated, with adverse effects being usually minimal or medium, thus not requiring treatment interruption. The presence of severe side effects imposed a break in the administration of the antiepileptic drug responsible for their occurrence and the modification of the therapeutic regimen. Patients who received antiepileptic therapy in polytherapy had more frequent adverse effects than those who undergone monotherapy. The presence of adverse events has an undeniable negative effect on the quality of life of children diagnosed with epilepsy.

NEWS

A PERSPECTIVE ON NANOPARTICLE UNIVERSAL INFLUENZA VACCINES

Annually recurring seasonal influenza causes massive economic loss and poses severe threats to public health worldwide. The current seasonal influenza vaccines are the most effective means of preventing influenza infections but possess major weaknesses. Seasonal influenza vaccines require annual updating of the vaccine strains. However, it is an unreachable task to accurately predict the future circulating strains. Vaccines with mismatched strains dramatically compromise the vaccine efficacy. In addition, the seasonal influenza vaccines are ineffective against an unpredictable pandemic. A universal influenza vaccine would overcome these weaknesses of the seasonal vaccines and abolish the threat of influenza pandemics. One approach under investigation is to design influenza vaccine immunogens based on conserved, type-specific amino acid sequences and conformational epitopes, rather than strain-specific. Such vaccines can elicit broadly reactive humoral and cellular immunity. Universal influenza vaccine development has intensively employed nanotechnology because the structural and morphological properties of nanoparticles dramatically improve vaccine immunogenicity and the induced immunity duration. Layered protein nanoparticles can decrease off-target immune responses, fine-tune antigen recognition and processing, and facilitate comprehensive immune response induction. Herein, we review the designs of effective nanoparticle universal influenza vaccines, the recent discoveries of specific nanoparticle features that contribute to immunogenicity enhancement, and recent progress in clinical trials (Lei Deng and Bao-Zhong Wang. A Perspective on Nanoparticle Universal Influenza Vaccines. *ACS Infect Dis* 2018; 4(12): 1656-1665).

OVARIAN ENDOMETRIOSIS AND VITAMIN D SERUM LEVELS

The aim of this study was to assess the vitamin D serum level in women with ovarian endometriosis; specifically, a possible correlation between the dimensions of ovarian endometriomas and vitamin D serum levels was evaluated. This was an observational study of childbearing-age women diagnosed with singleton ovarian endometrioma. Women diagnosed with multiple ovarian endometriomas or extraovarian endometriosis were excluded. Results: Forty-nine women constituted the initial study cohort. In these women, the mean 25-OH-D3 serum level was 22 ng/mL, and 42 of them (85,7%) were diagnosed with “hypovitaminosis D women” the mean diameter of ovarian endometriomas was 40.2±22.6 mm while in the “normal vitamin D serum level women” it was 26.7.12,1 mm. However, a significant linear correlation between 25-OH-D3 serum level and the diameter of ovarian endometriomas was found. (Ciavattini A, *et al. Gynecol Endocrinol* 2017; 33(2):164-167).

BLEEDING EVENTS IN PATIENTS WITH HCV- RELATED LIVER CIRRHOSIS TREATED WITH DIRECT ACTING ANTIVIRALS - FACT OR NATURAL COURSE ?

BLEEDING EVENTS IN PATIENTS WITH HCV- RELATED LIVER CIRRHOSIS TREATED WITH DIRECT ACTING ANTIVIRALS-FACT OR NATURAL COURSE ? (Abstract) **Aim**: We aimed to assess the incidence and risk factors of bleeding events in cirrhotic patients with sustained virological response (SVR) treated with direct-acting antivirals (DAAs) therapy. **Material and methods:** We retrospectively analyzed a cohort of patients with HCV-related liver cirrhosis treated with paritaprevir/ritonavir, ombitasvir and dasabuvir(PrOD) ± ribavirin and ledipasvir/sofosbuvir (LED/SOF) ± ribavirin for 12/24 weeks, in a tertiary gastroenterology referral center from North-Eastern Romania, between January 1st2016 and January 1st, 2019. All patients with presumption of digestive bleeding (hematemesis or melena) were evaluated and confirmed by upper digestive endoscopy. Patients known with thrombophilia were not included in the study group. **Results:** The study included 874HCV-infected cirrhotic patients treated with PrOD or LED/SOF ± RBV, with documented SVR, mean age 58,7±6,2years, predominantly female (58%). Of the total number, 443 (50.68%) received PrOD and 431 (49.31%) patients were treated with LED/SOF ± RBV. From all, 572 (65.34%) patients had Child-Pugh class A, 226 (25.96%) class B and 76 (8.7%) class C cirrhosis. Mean period from SVR and the occurrence of bleeding events was 230±121 days. Bleeding complications after SVR were reported in 16(1.83%) patients: 9 (56.25%) with variceal hemorrhage and7 (43.75%) with non-variceal hemorrhage. There was no significant change in prothrombin serum levels (baseline values in patients treated with PrOD was 11.67 ± 0.91 versus 11.70 ± 0.83 at SVR, p=0.993, respectively 11.5 ± 0.84 sec at baseline versus 11.4 ± 0.68 at SVR, p=0.715 in patients treated with LED/SOF+RBV) and platelet count (126 000 (101 500-162 000)*vs*. 131 000 (101 000-165 000), p=0.818 in patients treated with PrOD, respectively 94857.14±32 *vs*. 92428.57 ± 35, p= 0.853, in patients treated with LED/SOF+RBV).**Conclusions**: Bleeding events in patients with HCV-related liver cirrhosis treated with DAAs are not influenced by the variations of coagulation parameters, rather correspond to the hemodynamic changes induced by the status of advanced liver disease. It should be underlined that the bleeding events were mostly variceal bleeding, due to persistent portal hypertension despite viral eradication. **Keywords**: DIRECT ACTING ANTIVIRAL THERAPY, SUSTAINED VIROLOGIC RESPONSE, BLEEDING COMPLICATIONS, LIVER CIRRHOSIS.

The complications of liver cirrhosis frequently occur in the evolution of the disease, with a negative impact on the prognosis of patients.

In daily practice, we frequently meet cirrhotic patients who associate bleeding complications, especially variceal bleeding sustained biologically by prolonged bleeding and coagulation times, which is why it was assumed that these patients are characterized by a state of hypocoagulability induced by the deficiency of coagulation factors (1, 2).

Although thrombotic events may occur in the development of liver cirrhosis, bleeding is much more frequent and is based on a complex mechanism that involves increased pressure in the portal system, changes in vascular endothelium and coagulation disorders (3).

The vascular endothelium plays a central role in the pathophysiology of portal hypertension and in the control of coagulation. Physiologically the hepatic sinusoidal endothelial cells are different from the rest of the endothelial cells in the body because they have fenestrations, do not have platelet adhesion molecules (PECAM1 or CD31), E-selectin, and have no basement membrane. Capillary hepatic sinusoids determine their transformation into vascular endothelial cells with loss of fenestration, basal membrane formation, and expression of new surface adhesion molecules. All these changes contribute to an increased resistance to flow and the development of portal hypertension in cirrhotic patients (4).

The bleeding complications encountered in cirrhotic patients may be due to portal hypertension (bleeding from the esophageal, gastric, ectopic varices, portal gastropathy) or, in the advanced stages of the disease, by the status of hypocoagulability that could be associated with the appearance of cutaneous, mucosal or intracranial bleeding(5).

Portal pressure, assessed by hepatic venous pressure gradient (HVPG) measurement, determines the development of liver-related complications and mortality in patients advanced chronic liver disease. Variceal bleeding is one of the most severe complications associated with liver cirrhosis, being the most significant complication of portal hypertension, which is associated with a high early mortality (20% at 6 week)(6).

Since the onset of esophageal varices, the risk of bleeding is mainly related to local hemodynamic factors and mechanical parameters such as the pressure gradient between the hepatic vein and the portal vein, the degree of varicose veins, the presence of *cherry spots* and the severity of liver cirrhosis (7).

Direct-acting antivirals (DAAs) have radically changed the management of chronic HCV infection over the past years through high effectiveness and safeness, with a major impact on the prognosis and burden of the disease. The DAAs mechanism of action directly targets viral protease, polymerase and nonstructural proteins, thus allowing a high rate of viral clearance without significant side effects (8).

Sustained virologic response (SVR) is now achieved in >90% of the patients and is associated with improvements in liver function, fibrosis and overall survival. Portal hypertension is also expected to improve with virological response, along with the improvements in liver inflammation and liver fibrosis (9). The knowledge of the effects of hepatitis C virus (HCV) elimination on clinically significant outcomes like portal hypertension and its

complications is thus of unremarkable importance since it can influence management after SVR (10).

Recent studies have shown the positive impact on liver function, as measured by the CHILD-PUGH and MELD score, as well as the decompensation rate after obtaining SVR with the new oral direct-acting antivirals, but there are no conclusive data regarding the effect on clotting disorders due to liver cirrhosis (11). In our study, we aimed to assess the incidence and risk factors of bleeding events in cirrhotic patients with SVR treated with DAAs therapy.

MATERIALS AND METHODS

This is a retrospective study in which we included patients with HCV-related liver cirrhosis which fulfilled the criteria for antiviral therapy, conducted in a tertiary gastroenterology referral center from North-Eastern Romania, between January 1st, 2016 and January 1st 2019. The inclusion and exclusion criteria was according to our National Protocol. The regimens used were: Paritaprevir/Ritonavir, Ombitasvir and Dasabuvir (PrOD) ± Ribavirin in patients with HCV-related compensated liver cirrhosis (LC) and Ledipasvir/Sofosbuvir (LED/SOF)+Ribavirin (RBV) for 12/24weeks, in patients with compensated and decompensated LC. Diagnosis of cirrhosis was established based on clinical features, blood tests and imaging methods.

The study protocol was approved by the Ethical Research Committee of "Grigore T. Popa" University of Medicine and Pharmacy Iasi and by the Ethical Committee of the "Sf. Spiridon" County Clinical Emergency Hospital. All patients were required to sign an informed consent.

The diagnosis of liver cirrhosis was established by abdominal ultrasound (Philips HD 11xe ultrasound system) and non-invasive techniques for assessing liver fibrosis (Fibroscan and Fibromax). Blood tests were performed at baseline,at12/24 weeks after end of treatment (sustained virological response- SVR12) and during the presentation for digestive bleeding. All patients with presumption of digestive bleeding (hematemesis or melena) were evaluated and confirmed by upper digestive endoscopy performed in emergency and blood samples.

Statistical analysis. Data collected was statistically analyzed using *SPSS 20.0* (Chicago, IL, SUA). tests were two-tailed with p-value <0.05 was considered statistically significant. The quantitative variables were compared using the t-Student test, and the qualitative parameters were evaluated by the chi-square test.

RESULTS

The study included 874 HCV-infected cirrhotic patients treated with PrOD or LED/SOF± RBV, between January 1st, 2016 and January 1st, 2019, with documented SVR, mean age58,7 ± 6,2 years, predominantly female (58%). Of the total number, 443 (50.68%) received PrOD and 431 (49.31%) patients were treated with LED/SOF ± RBV. From all, 721 (82.49%) had compensated LC and 153 (17.50%) had decompensated LC. Child-Pugh score at baseline was 8.64 ± 1 in the LED/SOF ± RBV group versus 5.06±0.24 points (tab. I).

All patients had SVR documented by undetectable HCV-RNA. In patients treated with PrOD, GGT, AST and ALT had significant decreased values at SVR12 compared to baseline (p<0.001). Also, in the LED/SOF±RBV group, transaminases levels had an improving trend (p<0.001) (tab II, III).

TABLE III

Dynamic of biochemical parameters in patients treated with LED/SOF at baseline *vs.* SVR12

Parameters	Baseline	SVR12	P
PLT (mm^3), (mean ± SD)	94857.14 ± 32	92428.57 ± 35	0.853
INR, (mean ± SD)	1.28 ± 0.12	1.20 ± 0.08	0.05
TP (mean ± SD)	11.5 ± 0.84	11.4 ± 0.68	0.715
ALT (U/L), (mean ± SD)	86 ± 49.72	24.07 ± 13.33	< 0.001
AST (U/L), (mean ± SD)	76 ± 32.45	25 ± 18.29	< 0.001
GGT (U/L), (mean ± SD)	43.64 ± 19.66	33.71 ± 15.34	0.148
BT (MG/dL), (mean ± SD)	2.05 ± 0.66	1.50 ± 0.71	0.044
Creatinine (mg/dL) (mean ± SD)	0.7 ± 0.22	0.73 ± 0.15	0.626
Hb (g/dL), (mean ± SD)	12.82 ± 1.51	13.17 ± 1.50	0.544
Albumin (g/L), (mean ± SD)	3.30 ± 0.52	3.71 ± 0.39	0.026
MELD (mean ± SD)	12.46 ± 3.07	9.5 ± 3.32	0.024

Mean period from SVR and the occurrence of bleeding events was 230±121 days.

Bleeding complications after SVR were reported in 16 (1.83%) patients: 9 (56.25%) with variceal hemorrhage and 7 (43.75%) with non-variceal hemorrhage (3 (18.75%)- portal hypertensive gastropathy, 2 (12.5%)- gastric ulcer,1(6.25%)- duodenal ulcer, 1 (6.25%)- Mallory-Weiss syndrome). Four patients had previous episodes of variceal hemorrhage before initiating direct antiviral therapy (fig.1).

From all patients, 572 (65.34%) patients had LC Child-Pugh class A, 226 (25.96%) class B and 76 (8.7%) class C cirrhotic patients (fig. 2).

There was no significant change in prothrombin serum levels in both groups: baseline values in patients treated with PrOD was 11.67±0.91 versus 11.70±0.83at SVR, p=0.993, respectively 11.5±0.84 sec at baseline versus 11.4±0.68 at SVR, p=0.715 in patients treated with LED/SOF + RBV (fig.3).

Platelet count had no significant changes at baseline versus SVR in both groups (126 000 (101 500-162 000) *vs*. 131 000 (101 000-165 000), p= 0.818 in patients treated with PrOD, respectively 94857.14±32 *vs*. 92428.57±35, p= 0.853, in patients treated with LED/SOF+RBV) (fig. 4).

DISCUSSION

The last few years brought an important change in the therapeutic management of chronic HCV infection. Direct antiviral agents (DAAs) are highly effective and safe and are changing the prognosis and burden of the disease. Sustained virologic response (SVR) is now achieved in more than 90% of cases and is associated with improvements in liver function, fibrosis and overall survival (12).

In order to accomplish the goal of HCV elimination as an important health public threat by 2030, HCV treatment is nowadays recommended in almost all infected patients, even those without significant fibrosis. This, together with the high SVR rates and the safety profile of DAAs, can change the history of HCV infection and improve clinical outcomes namely by avoiding the development of portal hypertension and improving it in patients with patients with established portal hypertension (13).

Although thrombotic events may occur in the natural course of liver cirrhosis, bleeding is much more frequent in clinical practice. The available data from the last few years showed that there is an imbal-

ance concerning the hemostasis status in cirrhotic patients which are considered to be predisposed to bleeding events; many studies have demonstrated a disturbance of the balance between pro- and anticoagulants factors in cirrhotic patients. There are very few studies regarding the coagulation status of cirrhotic patients with SVR treated with DAAs (11). In our study we aimed to assess the incidence and risk factors of bleeding events in patients with SVR treated with DAAs.

Our study showed an incidence of 1.83% of bleeding events in patients with HCV related liver cirrhosis treated with DAAs.

There was a slight improvement of platelet count after SVR in patients treated with PrOD, but not significantly statistic. We didn't find any improvement in platelet count at SVR compared to baseline in patients treated with LED/SOF+RBV, but on the contrary we identified a slight decrease in platelets that can be explained by splenic sequestration and exaggerated destruction, representing a characteristic status in patients with advanced liver disease. Studies that used radiolabeled platelets have shown a low survival to which is added the low level of thrombopoietin, determined by a decreased synthesis in liver cirrhosis. Tripodi *et al* (14), did not found an appreciable increase in platelet count in their study lot, incriminating the short period of follow-up and the fact that viral eradication and improvement of liver function does not change the splenic pool. None of the currently used coagulation parameters in cirrhotic patients (PT, INR) had a notifiable statistic change. This finding confirms the idea that the anticoagulant status in cirrhotic patients cannot be reflected only by these laboratory parameters.

The majority of biochemical parameters showed an improvement on SVR12 compared to baseline. Transaminases and GGT had significantly decreased values in both groups of patients, revealing the disappearance of continuous liver injury due to the viral clearance. Also, we observed a decreasing trend for MELD score, showing an improvement in global liver function.

The evaluation of the severity of the liver disease according to the Child-Pugh score (CPS) demonstrated that the majority of the patients who had variceal hemorrhage were in the moderate and severe stages (CPS class B/C).

The assessment of the risk of development or of the prognosis of bleeding of esophageal varices, depending on the ratio between the spleen/platelet diameter, showed that the majority of patients who had variceal hemorrhage had a value > 3.

The bleeding events were mostly variceal bleeding, which is in fact and rightly the cause of portal hypertension; despite SVR liver fibrosis remains, portal hypertension remains and thus the risk of bleeding.

The clinical use of hepatic venous pressure gradient (HVPG) measurement is limited by its invasiveness. Moreover, its availability is mostly restricted to academic centers. Thus, the non-invasive monitoring of the regression of liver fibrosis and portal hypertension after HCV eradication will be a major challenge in the post-HCV era.

A well-designed retrospective study conducted by Libânio and Marinho (15), evaluated the changes in HVPG and liver stiffness in 60 cirrhotic patients (84% Child A) treated with various combinations of DAAs. SVR led to a reduction in HVPG in 80% of the patients. This beneficial effect was found in all strata of HVPG, although

portal hypertension was less likely to improve in Child B patients; therefore, a point of no return seems to exist from which viral elimination is no longer capable of preventing portal hypertension progression and liver decompensation.

Although non-invasive methods cannot substitute HVPG measurement, non-invasive evaluation of liver fibrosis by transient elastography (Fibroscan) and serological tests (Fibromax and APRI test) showed that patients with variceal hemorrhage had decreased hepatic stiffness after SVR, but with a preservation value above 12.5 kPa, which shows that liver fibrosis remains after SVR, portal hypertension remains and thus the risk of bleeding (16).

According to Calvaruso V *et al*. (17), although portal hypertension improves in the majority of people with hepatitis C and cirrhosis after hepatitis C is cured, not all patients experience improvement, and esophageal varices may continue to progress despite successful hepatitis C treatment.

What is less clear is how frequently portal hypertension and varices improve after hepatitis C is cured. Two studies presented at The International Liver Congress (Paris, 2018) reported on the evolution of these conditions and attempted to identify predictors of regression or progression (18).

Puente Á *et al.*(19), found that clinically significant hypertension persisted in 68% of people with cirrhosis cured of hepatitis C, despite a significant improvement in liver stiffness. Persistence of portal hypertension was associated with a higher hepatic venous pressure gradient and a smaller reduction in liver stiffness, which involve an increased risk of variceal bleeding.

Another study conducted by Sabela *et al*. (20), showed that once patients develop cirrhosis with severe portal hypertension (HVPG $\geq$ 10 mmHg), regardless of SVR in hepatitis C therapy, they remain at risk for hepatic decompensation within the first 5 years after treatment.

Due to the novelty of DAAs therapies (and thus short follow up times) there are only few studies assessing the effects of HCV novel treatments on portal hypertension and clinical decompensation. In patients successfully treated with DAAs, MELD and CHILD-PUGH scores were shown to improve, fact also demonstrated by the literature data (21).

Future studies should focus on predictors of portal hypertension resolution, as it may influence management and monitoring in the subset of patients with a high probability of having clinically significant portal hypertension after treatment, objectified by the appearance of bleeding causes variceal as well as by the portal hypertensive gastropathy.

CONCLUSIONS

Bleeding events in patients with HCV-related liver cirrhosis treated with DAAs are not influenced by the variations of coagulation parameters, rather correspond to the hemodynamic changes induced by the status of advanced liver disease. It should be underlined that the bleeding events were mostly variceal bleeding, which is in fact and rightly a consequence of portal hypertension; despite SVR liver fibrosis remains, portal hypertension remains and thus the risk of bleeding.

It remains to be further demonstrated if the mechanism of DAAs can influence the development of bleeding events in these patients or are part of the natural course of advanced liver disease.

VIRAL PATOLOGY AND ORAL MANIFESTATION (Abstract): Although the medical and biological importance of ringworm infections was acknowledged a long time ago, the putting-up-to-date of some clinical notions is justified for at least three reasons: the improvement and accessibility of molecular biology techniques, the consideration of the major pathogenic role of these viruses in circumstances of immune depression, the possibility to control these infections by means of specific chemotherapy. **Material and method**: A prospective study was carried out in the interval 1.01.2006 – 31.12. 2008, of all cases of ringworm infections with oral eclat, hospitalised in Infectious Diseases Hospital Iaşi. The diagnosis was established according to the clinical manifestations, the hematological modifications and, if the case, serological examination. **Results**: The study included 291 cases.The infection with EVB (infectious mononucleosis) was diagnosed within the age interval 8 months–60 years (median–10 years). The oral manifestations were mainly located at the level of the palatine and velopalatine vault. Chickenpox was diagnosed within the age interval 7 days–52 years (median–8 years). The chickenpox enantem was observed in 90.42% of the cases, being represented by varix wounds, or "hemorrhagic spots", mostly located at the level of the fibrous mucose membrane of the palatine vault – 40.2%. **Conclusions**: The knowledge of the oral manifestations in ringworm infections with highly contagious potential and a high risk of severe complications represents a fundamental method in early diagnosis as well as an important step in establishing the prophylaxy measures meant to prevent these pathogens from being transmitted to the dentist office. **Key words**: EPSTEIN-BARR VIRUS, VARICELO-ZOSTERIAN VIRUS, HERPES SIMPLEX VIRUS

IS THERE A ROLE FOR A NEW SET OF PROGNOSTIC MARKERS IN ACUTE PANCREATITIS?

IS THERE A ROLE FOR A NEW SET OF PROGNOSTIC MARKERS IN ACUTE PANCREATITIS? (Abstract): The lymphocyte-monocyte ratio, platelet-lymphocyte ratio and neutrophil-lymphocyte ratio are parameters that are simple and may easily benefit to assess the inflammatory condition of a patient that is suspected of having acute pancreatitis. **Material and methods***:* In a group of 337 patients, laboratory and imaging investigations were performed to diagnose and determine the severity score of acute pancreatitis and lymphocyte-monocyte ratio, platelet-lymphocyte ratio and neutrophil-lymphocyte ratio. **Results:** The mean for neutrophil-lymphocytes ratio and for platelet-lymphocyte ratio in patients without complications were lower compared to patients with complications. **Conclusions:** It is important for patients to be aware of the evolutionary stage and to follow the treatment and the appointment and make an abdominal or pancreatic CT scan with contrast to control and prevent complications with late onset. Determining neutrophil-lymphocytes ratio, platelet-lymphocyte ratio and lymphocyte-monocyte ratio is a simple investigation and can help control and prevent complications with late onset. **Keywords:** ACUTE PANCREATITIS; LYMPHOCYTE; NEUTROPHIL; PROGNOSIS; NEUTROPHIL-LYMPHOCYTE RATIO.

Acute pancreatitis (AP) is histologically defined as an acute inflammatory process of the pancreas, varying from interstitial edema to necrosis of the parenchyma and peripancreatic tissues. AP can range from mild disease requiring mainly supportive therapy, occurring in the majority of cases, to severe condition with major, potentially fatal complications.

According with the revised Atlanta classification, acute pancreatitis is classified as mild acute pancreatitis (MAP), moderate severe acute pancreatitis (MSAP) and severe acute pancreatitis (SAP) (1).

In the treatment of AP, an early determination of severity is an important factor. The assessment of the severity of pancreatitis is made standardized by severity scores, biological markers and imaging explorations. The neutrophil-lymphocyte ratio (NLR) is an inflammatory status parameter that has been used as a prognostic factor for various cardiovascular (2, 3) or neoplastic diseases, such as esophageal,

lung, colorectal, and pancreatic cancer (4-6), as well as a strong predictor for postoperative complications (7-9).

The platelet-lymphocyte ratio (PLR) is also a simple parameter that can be used to assess the inflammatory status and the prognosis of patients with acute pancreatitis, especially in case of acute gallstone pancreatitis (10). PLR has also been used as an efficient predictor marker of mortality and morbidity after heart transplantation, obstetrical conditions, and stroke (11-13).

The lymphocyte-monocyte ratio (LMR) is a less studied parameter that can be used to assess the inflammatory condition of a patient suspected of having acute pancreatitis (14, 15). It has been used to predict the evolution of tumors, in oncohematology, and myocardial infarction (16-18).

The role of NLR, PLR and LMR as predictors in acute pancreatitis has not been thoroughly studied, and they may offer a simple and efficient tool for assessing the severity of the disease.

In this study we investigated the role of NLR, PLR, and LMR as predictors in complicated and uncomplicated forms of acute pancreatitis.

MATERIAL AND METHODS

A retrospective analysis of all patients admitted for acute pancreatitis between 1st of January 2013 and 31st of December 2017 in the Ist Clinic of Surgery of Craiova Emergency University Hospital was conducted in order to identify those patients which developed specific complications during their hospital stay. The cases were structured in two subgroups: uncomplicated cases (group 1) and complicated cases (group 2).

The information was collected from the electronic database of the hospital, as well as from the medical registries and medical files of the patients.

The data collected included: Balthazar score, lymphocytes, neutrophils, platelets, monocyte, complications, co-morbidities.

Inclusion criteria were acute abdominal pain, elevated serum enzymes and urinary pancreatic enzymes and / or radiological evidence of pancreatitis

Exclusion criteria were patients with sepsis, infections, pneumonia, chronic inflammatory diseases, chronic myocardial infarction or patients with incomplete clinical and paraclinical data.

Complications that have been considered were local pancreatic complications have been defined as acute development of peri-pancreatic fluid collection, pancreas pseudocyst, acute necrotic collections and wall-off necrosis, visualized by computed tomography (1, 19, 20). Systemic complications have been defined as exacerbation of pre-existing co-morbidity, such as coronary artery disease or chronic pulmonary disease.

All relevant data were collected into Microsoft Excel database. Statistical analysis of the results was performed using *SPSS version 20*. We compared the values of NLR, PLR and LMR for patients in the two subgroups by using independent samples t-test, the cut-off value using ROC curve and Chi-square for odd ratio, in order to determine a maximum normal limit with the goal of improving the specificity and sensibility of these parameters as predictors for early complications. We considered p-values of < 0.05 to be statistically significant.

The statistical analysis has considered several parameters, such as the degree of

severity, the value of the neutrophil-lymphocyte ratio, platelet-lymphocyte ratio and lymphocyte-monocyte ratio, as well as the overall complication rate.

RESULTS

Only 58 (17.21%) from the 337 patients had complications, with a mortality rate of 8.90% (29 patients).

Cardiovascular disease represented 35% of the co-morbidities, the most common cardiovascular disease being hypertension, followed by atrial fibrillation and chronic heart failure. Other co-morbidities were pancreatic fistula, oral or gastrointestinal cancer, diabetes.

The mean value of neutrophil-lymphocytes ratio in uncomplicated patients was 6.38, compared to the complication group of 18.33 with $p < 0.001$ at independent samples t-test (tab. I, fig. 1). We determined that for a cut-off value of 9.14 for NLR the sensitivity resulted 81% and the specificity was 76.7%, with a Chi-square odd ratio for developing complications by 8.58. The NLR is an inflammatory marker that can be used to predict the occurrence of acute pancreatitis with a surface over the Receiver Operating Characteristic (ROC) of 0.830 (0.766-0.894) ($p < 0.001$); (fig. 2).

NLR without complications *vs.* with complications

	NLR without complications	**NLR with complications**
Sample size	279	58
Arithmetic mean	6.3887	18.3302
Standard deviation	5.6098	13.5644
Cut-off value (ROC Curve)	**9.1483**	
independent samples t test	P < 0.001	

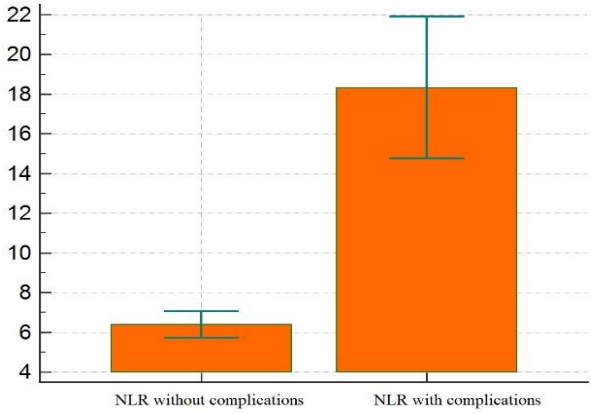

Fig. 1. NLR without complications *vs.* with complications

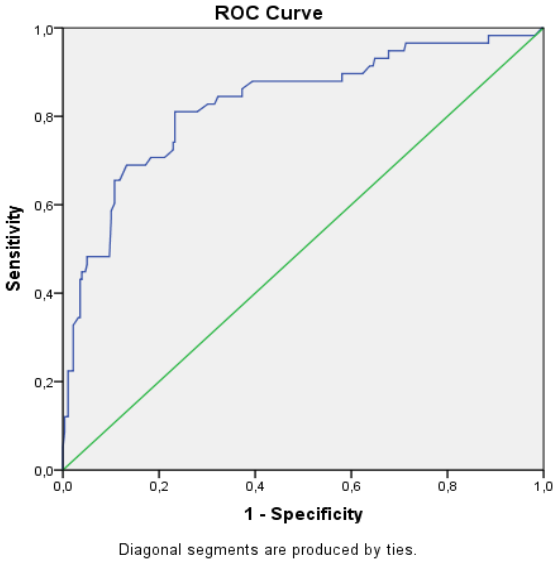

Fig. 2. ROC for NLR without complications *vs.* with complications

The mean platelet-lymphocyte ratio in patients without complications was 141.56 compared to 175.97 for the patients with complications (p=0.021) (tab. II, fig. 3). We determined that for a cut-off value of 123.82 the sensitivity resulted 72.4%, but with a low specificity of 47%, with a Chi-square odd ratio for developing complications by 1.88. The PLR is a marker that show inflammation and can be used to predict acute pancreatitis occurrence with a surface over the Receiver Operating Characteristic (ROC) of 0.587 (0.501-0.673) (p=0.037); (fig. 4).

The mean lymphocyte-monocyte ratio of 3.8 resulted for patients without complications compared with value 2 for patients with complications (Table 3, Graph 5). We determined that for a LMR cut-off value of 1.88 the result for sensitivity was 66% and specificity was 72.9%, with a Chi-square odd ratio for developing complications by 3.56. The LMR can be used as an inflammatory marker that can predicted the occurrence of acute pancreatitis with a surface over the Receiver Operating Characteristic (ROC) of 0.303 (0.229-0.377) (p <0.001); (Graph 6).

DISCUSSION

Patients with acute pancreatitis usually recover without having further complications, but patients that have severe form of acute pancreatitis, in evolution, may develop serious complications (such as pancreatic infection, bile obstruction, pseudocysts, pancreatic duct obstruction, pancreatic necrosis, pulmonary edema, splenic vein thrombosis, adult respiratory distress syndrome). It is important for patients to be aware of the evolutionary stage and to follow the treatment and to accept the appointment and realization of an abdominal or pancreatic CT scan with contrast to control and prevent complications with late onset. Determining neutrophil-lymphocytes ratio, platelet-lymphocyte ratio and lym-

phocyte-monocyte ratio is a simple investigation and can help control and prevent complications with late onset.

Thirty-five percent of patients were diagnosed with severe acute pancreatitis. The overall mortality rate was 8.90% of all cases in the study group.

Only twenty-five percent of patients didn't suffer from co-morbidities, which could explain the mortality rate. Cardiovascular disease represented 35% of the co-morbidities, the most common cardiovascular disease being hypertension, followed by atrial fibrillation and chronic heart failure.

Eighteen percent patients developed complications: patient under treatment with anticoagulant, patients under platelet anti-aggregant treatment, patients requesting discharge on request, patients that developed pancreatic fistula, patient leaving the hospital without the agreement of the medical staff, death.

Patients should be made aware of their evolutionary status and follow a treatment, accepting an imaging investigation such as abdominal CT or pancreatic CT scan to control and prevent the onset of complications with late onset.

Different genetic mutations (p.N34S in SPINK1) may be predisposing for acute pancreatitis, mostly alcohol induced acute pancreatitis, and could develop a more severe form of acute pancreatitis (21). One study suggests a risk for developing acute pancreatitis for patients having colorectal cancer that are undergoing chemotherapy with FOLFOX6 (22).

Since blood counts are routinely performed on admission, determining the neutrophil ratio of lymphocytes is a simple, quick and inexpensive investigation that can help to control and prevent complications with late onset.

The role of NLR, PLR and LMR as predictors in acute pancreatitis has not been thoroughly studied and may offer a simple and efficient tool for assessing the severity of the disease.

The NLR is a simple parameter that has been used as an inflammatory or infectious predictor and marker in various pathologies and postoperative complications (8, 9).

The PLR is also a simple parameter that can be used to assess easily the inflammatory condition of a patient suspected of having acute pancreatitis, specially to predict acute gallstone pancreatitis (10).

The LMR is an easy and simple parameter that can be used to assess the inflammatory condition of a patient suspected of having acute pancreatitis.

The mean value for NLR in patients without complications was found to be lower compared with that of the patients with complications.

The PLR mean for patients with complications was found to be higher than in patients without complications.

Patients without complications had a higher mean LMR than patients with complications.

Forget *et al*. determined that normal NLR values in a non-geriatric adult (21 to 66 years of age) in the healthy population are between 0.78 and 3.53 (23).

Most patients had multiple other health problems or came in an advanced stage of acute pancreatitis, and so they had a high NLR value. Like Azab B *et al.* (24) suggested that patients with NLR above 7.6 have more than one presentation in the ICU and suggest using an NLR limit value above 4.7 as a simple indicator of severity in patients presenting with acute pancreatitis.

The cut-off value for NLR mean was 9.14 with a sensitivity of 81% and specific-

ity of 76,7% with an odd ratio for developing complications by 8.58. The cut-off value for PLR mean was 123.82 with a sensitivity of 72.4% and specificity of 47% with an odd ratio for developing complications by 1.88. The cut-off value for LMR mean was 1.88 with a sensitivity of 66% and specificity of 72.9% with an *odd ratio* for developing complications by 3.56.

CONCLUSIONS

Determining the neutrophil to lymphocytes ratio, platelet-lymphocyte ratio and lymphocyte-monocyte ratio are a quick, simple and inexpensive investigation that can help to control and prevent complications with late onset.

Patients with complicated acute pancreatitis had a higher mean value for neutrophil-lymphocytes ratio and platelet-lymphocyte ratio. Patients without complications had a higher mean LMR than patients with complications.

The following cut-off values for over which it is more likely to have complications have been found: NLR mean > 9.14, PLR mean > 123.82, LMR mean < 1.88.

INFECTION AND PREGNANCY - THE EXPERIENCE OF THE HOSPITAL OF INFECTIOUS DISEASES IASI IN 2018 (Abstract). **Aim**: To evaluate the incidence of different infections diagnosed in the pregnant women admitted at the "Sf. Parascheva" Clinical Hospital of Infectious Diseases, from Iasi. **Material and methods**: We conducted a retrospective study using the hospital-based medical records of the pregnant patients admitted in our hospital. We analyzed clinical and paraclinical data regarding symptomatology, treatment and evolution. **Results:** In 2018, 11 707 patients were admitted to the clinic, of which 6 102 were female. 102 of them were pregnant women (1.67%) diagnosed with a variety of conditions. Specifically, 52.94% suffered from respiratory tract infections (including bacterial pneumonia, interstitial pneumonia, confirmed influenza, tracheobronchitis), 15.68% had urinary tract infections, and 15.68% presented digestive pathologies. Symptomatic and antibiotic treatment was initiated, with a favorable evolution in 99% of cases. **Conclusions**: Pregnancy-related immunosuppression seems to predispose pregnant women to certain infections. **Keywords:** INFECTION, PREGNANCY, ANTIBIOTIC.

Pregnant women have been known for centuries to manifest a unique susceptibility to infectious diseases, which may lead to different outcomes compared to the general population and especially non-pregnant woman at childbearing age. It is thought that a combination of adaptive alterations in immunity combined with changes in anatomy and physiology accompanying pregnancy underpin this vulnerability (1). During pregnancy, several mechanical and pathophysiological changes occur (e.g. a decrease in respiratory volumes and urinary stasis due to an enlarging uterus) and immune adaptations are required to accommodate the fetus (2). Immunologic alterations during pregnancy may help explain the modified severity of and susceptibility to infectious diseases. As pregnancy progresses, hormone levels change dramatically and are considerably higher than at any other time. The interplay between sex hormones and the immune system is complex and multifactorial, and it affects many organ systems (3).

Several issues are pertinent with regard to the threat of infectious disease during pregnancy. First, as previously mentioned, pregnant women are more susceptible to infectious diseases due to the changes in

immunity and physiology brought about by the pregnancy itself. Second, the effects of infectious diseases on the fetus may be unknown and difficult to predict, and the diagnosis of infection in the fetus or infant can be challenging. Third, the standard approaches to prophylaxis and treatment appropriate for the general population may not be appropriate for pregnant women (4).

This retrospective analysis represents a first step towards a longer-term data collection regarding the most frequent infections during pregnancy, considering that we found no specific data about infections affecting pregnant women in North-East Romania.

MATERIAL AND METHODS

We conducted an observational retrospective study of the patients admitted to the "St Parascheva" Hospital of Infectious Diseases Iași over a 1-year period (January 1st, 2018 - December 31st, 2018). Only pregnant women admitted to this hospital were included in the study. Data regarding the symptomatology at the moment of presentation, paraclinical data, treatment administered, and subsequent evolution were collected from the hospital-based medical records of the patients.

Patients that presented to the triage room of the hospital but were not admitted to our clinic as well as HIV-positive women were excluded from the study. The follow-up of the discharged patients was performed by the obstetrician monitoring the pregnancy, and we are not aware of any further developments or consequences. Mention should also be made that not all infections of pregnant women are treated in our clinic, and the primary physician that the pregnant female approaches is usually her obstetrician. This can influence how accurately hospital data is able to reflect the real incidence of infections during pregnancy.

RESULTS

In 2018, 11 707 patients were admitted to the "Sf. Parascheva" Hospital of Infectious Diseases in Iași, Romania, of which 6 102 (52.12%) were female. The 102 pregnant women represent 1.67% of the total number of admitted female patients, the majority coming from the urban area (65.5%). We also noticed that 60.78% (62 cases) presented to our hospital in the cold months of the year (January and February, and from September to December) (fig. 1).

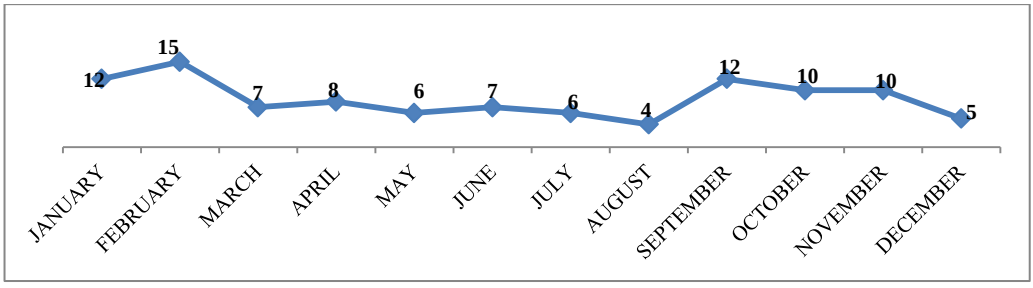

Fig. 1. Number of cases admitted by months

The pregnant patients' age ranged from 15 to 43 years old, with a mean age of 29.8 and the most affected age group being 26-35 . (fig. 2)

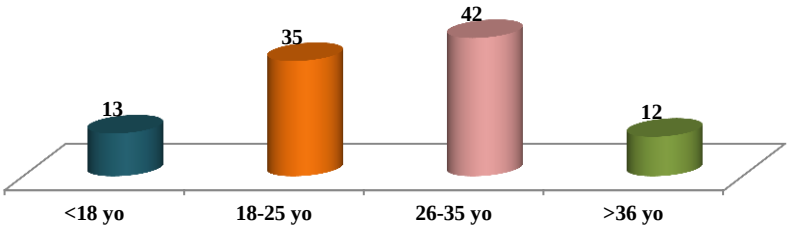

Fig. 2. Age categories

Regarding the pregnancy stage of the presenting women, there were no significant differences: 35 women were in the first trimester (34.31%), 40 were in the second (39,21%) and 27 in the third (26.47%).

The predominant symptomatology included shivers in 76 cases (74.5%), followed closely by fever in 65 cases (63.72%). The patients also complained of nausea (32 cases, 31.37%)), dysuria (18 cases, 17.6%), pollakiuria (16 cases, 15.68%), arthralgia and myalgia (7 cases, 6.8%).

The primary pathology that pregnant women were suspected upon admission to our hospital consisted of pneumonia in 31 cases (30.39%). In 10 of these cases (9.80%), the etiological agent was identified as *Streptococcus pneumoniae*, and in 6 cases (5.88%) it was *Hemophilus influenzae*. The other 15 cases (14.70%) were diagnosed as interstitial pneumonia.

Other respiratory pathology admitted in our hospital was tracheobronchitis (15 cases - 14.70%), seasonal influenza (5 cases - 3.92%) and bronchopneumonia (3 cases- 2.94%)

Apart from these, the respiratory pathology included tracheobronchitis (15 cases, 14.70%), seasonal influenza (5 cases, 3.92%) and bronchopneumonia (3 cases, 2.94%). Another pathology requiring admittance was urinary tract infection, present in 17 cases (16.66%). In most of them (12 cases, 11.76%), *Escherichia coli* was the causing agent, followed by *Klebsiella pneumoniae* (4 cases, 3.92%) and one case with *Staphylococcus saprophyticus.* Digestive symptoms were the main cause of presentation in another 16 cases (15.68%), of which 15 (14.70%) were due to severe gastroenteritis and of the other turned out to be food poisoning. The diagnosis of sepsis upon admittance was encountered in 11 cases (9.27%). Last but not least, 4 patients presented with different types of rashes: two cases of maculopapular rash were diagnosed as measles, one case of small bumps, blisters, and pustules was identified as chicken pox, and the other was a case of allergodermia.

Antibiotic or antiviral therapy was administered according to the clinical presentation and data from the antibiogram, in accordance with the European guidelines: Ampicillin, Amoxicillin, Clarithromycin, Ceftriaxone, Oseltamivir. In the majority of cases, the patients responded well to the treatment and their evolution was favorable. Only one patient with several prior comorbidities passed away after developing due to multiorgan dysfunction syndrome.

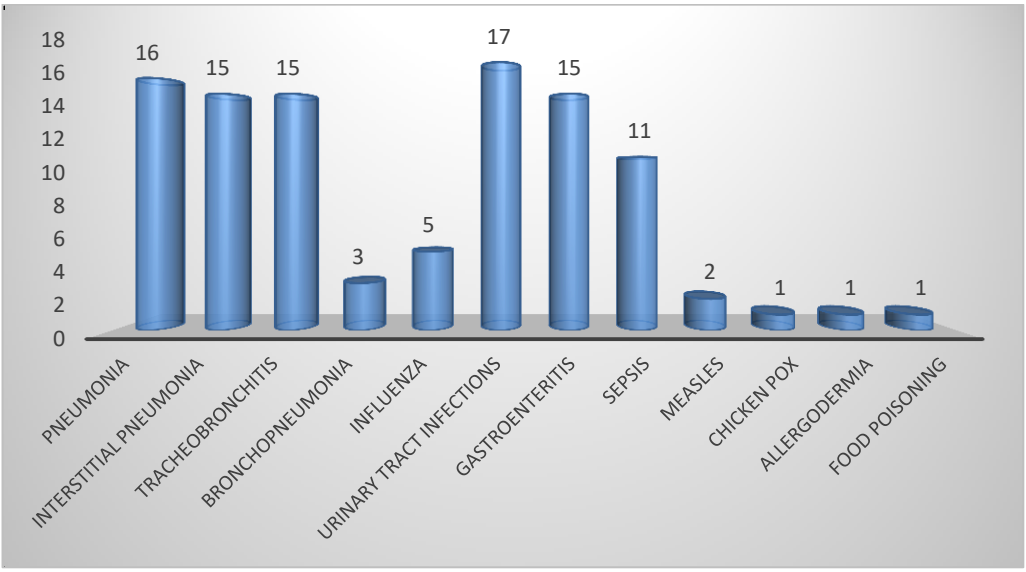

Fig. 3. Diagnosis at admittance

DISCUSSION

The most common upper respiratory disease, coryza, pharyngitis, and others, acts similarly in both pregnant and non-pregnant women, without affecting the fetus. Diseases of the respiratory system caused by acute infections are among the most common maternal diseases during pregnancy (5). In our study, the majority of cases which required admission were upper and lower respiratory infections, 54 (52.94 %)in all. The medium forms of respiratory infection hospitalized were represented by tracheobronchitis and interstitial pneumonia.

In the literature, bacterial pneumonia is most commonly attributed to the *Streptococcus pneumoniae, Hemophilus influenzae, Mycoplasma pneumoniae* (5). The signs (fever, crackles, abnormal breath sounds) and symptoms (cough, sputum production, dyspnea, pleuritic chest pain) of bacterial pneumonia in pregnancy are the same as in non-pregnant individuals.

In our study, the data showed that the primary etiological agent of bacterial pneumonia was *Streptococcus pneumoniae* (10 cases), followed closely by *Hemophilus infuenzae* (6 cases). The treatment was initiated empirically and then adjusted with the appropriate antibiotics according to the results of the antibiogram.

Pregnant women tend to suffer from more severe forms of illness and higher mortality from influenza than the general population. (6) This is theorized to be due to the physiologic changes brought about by the pregnancy, including decreased lung capacity, increased oxygen consumption, and decreased cell-mediated immunity (7). Studies on pregnant women in New York City, for instance, showed that the severity of illness and the timing of antiviral treatment are correlated, which would justify the early use of antivirals in cases of suspected or proven influenza infection (8, 9). The clinical presentation of influenza does

not seem to be altered by pregnancy; symptoms include cough, fever, malaise, rhinitis, myalgias and arthralgias, headache, chills (10).

In our study, five women diagnosed with influenza were admitted to hospital upon presenting with severe symptoms and low oxygen saturation. Their condition required specialized treatment and continuous observation, and the antiviral of choice was Oseltamivir together with specific support treatment.

Urinary tract infections (UTIs) are common in pregnant women and pose a great therapeutic challenge, since the risk of serious complications in both the mother and her child is high. At around week 6 of pregnancy, physiological changes occur, and the ureters begin to dilate (11). Although the incidence of bacteriuria in the pregnant population is only slightly higher than in non-pregnant women, its consequences for both the mother and the unborn child are more severe (12,13). Organisms causing UTI in pregnancy are the same uropathogens which commonly cause UTI in non-pregnant patients. Most infections are caused by *Enterobacteriaceae*, with *Escherichia coli* being responsible for 63-85% of cases, and the other culprits are *Klebsiella pneumoniae* (in approximative 8% of cases), coagulase-negative *Staphylococcus* (around 15%), *S. aureus* (up to 8%), and group B streptococci (up to 7%) (14-16). Our results are in accordance with the literature, *E.coli* being the primary etiological agent of UTIs found in three quarters of the samples (12 cases).

Studies have shown that gastroenteritis affects a large proportion of pregnant women. While gastrointestinal disease such as Crohn's disease (17) and untreated celiac disease (18) could affect neonatal outcomes, acute gastroenteritis during pregnancy has not been associated with any adverse outcomes for the newborn (except for a slight decrease in the duration of pregnancy and an increased risk of preterm birth in mothers with several episodes of gastroenteritis) (19). The signs and symptoms of viral gastroenteritis in pregnant women are no different from those reported by non-pregnant women, and they include diarrhea (> 3 watery stools/ day), nausea, vomiting. In our study, the hospitalized women showed dehydration signs and were admitted. In only one case a preterm birth was initiated, which required urgent transfer to the obstetrics and gynecology hospital.

According to numerous studies, pregnant women are at increased risk of morbidity and mortality associated with measles and are also more likely to develop pneumonia and to be hospitalized (20-24). The signs and symptoms of measles in pregnant women are usually similar with those in the general population, namely a prodrome of fever, cough, conjunctivitis malaise, coryza and the appearance of Koplik's spots towards the end of prodrome, followed by the appearance of a maculopapular rash which then spreads from the head to the trunk and ultimately down to the lower extremities. Fever and elevated liver enzymes were reported as more common among pregnant women with measles than among non-pregnant women suffering from the same illness (25).

Similarly, the clinical presentation of chicken pox is the same in pregnancy as generally. The infected patient will develop high fever accompanied by small bumps, blisters, and pustules (26). However, chickenpox during pregnancy may cause

fetal infections (27), and abnormalities diagnosed as congenital varicella syndrome are expected in about 12% of infected fetuses. Prospective studies have estimated the incidence of fetal and congenital varicella syndrome as 2.2% (28).

Last but not least, psychosocial stress and disruptive life events have been shown to affect birthweight and fetal development (29) enough to require the intervention of a hospital psychologist (30, 31).

CONCLUSIONS

Most of the pregnant women admitted to the hospital of infectious diseases from the city of Iași in NE Romania were diagnosed with mild forms of various pathologies. Adequate and timely treatment, together with careful monitoring, resulted in favorable outcomes in 99% of the cases.

Normally, pregnancy involves a certain degree of physiological adjustment and immunosuppression. Any febrile sign or symptom that points to an infectious disease requires an urgent response and a holistic approach involving the collaboration between obstetricians and specialists in infectious diseases. Early diagnosis followed by immediate and appropriate therapy is essential during pregnancy in order to avoid compromising maternal and neonatal health.

Because the effects of emerging infections in pregnant women may differ from those in the general population, pregnancy must be considered a potential risk factor for infectious disease and, if left untreated, even death.

POSTPROCESSED COMPUTED TOMOGRAPHY ANGIOGRAPHY IMAGES - AN UNDERUSED MODALITY OF BETTER UNDERSTANDING ANEURYSMS (Abstract): **Aim**: Intracranial aneurysms are the leading cause of non-traumatic subarachnoid hemorrhage which can have devastating consequences. Imaging techniques improved greatly and now play a very important role in detection and management of aneurysms. The aim of this study was to share our experience with applications of three-dimensional reconstructions from computed tomography angiography images for diagnosis and surgical planning of brain aneurysms. **Material and methods**: We retrospectively analyzed a series of 244 aneurysms in 210 patients treated from January 2019 to December 2019 in a specialized neurosurgical center. We used Toshiba Aquilion 32 slice CT scanner for image acquisition and Vitrea software for three dimensional reconstructions. **Results:** we found 244 aneurysms and the anterior communicating artery was the most frequent aneurysm location, followed by middle cerebral artery, the posterior communicating artery and internal carotid artery. Maximum Intensity Projection and volume rendering techniques provided for the neurosurgeons and neurosurgery residents a very good detection and assessment of aneurysm morphology with its proximal and distal vessels. **Conclusions:** Postprocessed images and three-dimensional reconstruction should be used more often in neurosurgery in order to better understand the morphologic details and for a better treatment planning of intracranial aneurysms. **Keywords**: POSTPROCESSED IMAGES, 3D RECONSTRUCTIONS, COMPUTED TOMOGRAPHY ANGIOGRAPHY, MAXIMUM INTENSITY PROJECTION, VOLUME RENDERING TECHNIQUE.

Intracranial aneurysms represent a serious medical condition defined by localized dilatations within the wall of cerebral arteries and are prone to rupture. The resulted subarachnoid hemorrhage (SAH) is associated with a high mortality and morbidity rate (1).

The ongoing neurosurgical progress with surgical and endovascular treatment techniques had a major impact in patient outcome and found an important place in case management (2). Important factors in treatment planning are the imaging techniques and three dimensional (3D) reconstructions used as tools for a better understanding of the morphology of the aneurysms.

Although sectional imaging was a revo-

lutionary discovery especially for brain and cerebral arteries evaluation, the lack of a third dimension (sagittal and coronal) can be a limitation in appreciating anatomy and pathology for many physicians, including neurosurgeons and mostly for inexperienced ones. Since the development of three-dimensional computer rendering algorithms in the 1970s this limitation could be overcome and used to make exceptional 3D reformats for a better treatment planning (3).

Computed tomography angiography (CTA) and magnetic resonance angiography (MRA) are used for an initial evaluation of cerebral vessels in case of an aneurysm suspicion even though the digital subtraction angiography (DSA) is the "gold standard" because they are less invasive techniques. Maximum intensity projection (MIP) and 3D volume rendering (3D VR) are very useful tools that can provide an overview of the aneurysm and this way help the neurosurgeon think to the best surgical approach.

In this article, through case studies and illustrations, we describe the use of tools for 3D reconstructions with MIP and VR techniques and also highlight their advantages, disadvantages and some of the pitfalls that can lead to misinterpretation.

MATERIAL AND METHODS

We analyzed retrospectively 244 aneurysms in 210 patients from January 2019 to December 2019 that were treated in a dedicated neurosurgery hospital that serves as a care center in Moldova region of Romania. All aneurysm were confirmed with DSA.

All imaging studies (CTA) were acquired in our hospital using a Canon (Toshiba) Aquilion 32 slice CT scanner (continuous slice with slice thickness of 0.5 mm with zero gap).

We selected a series of cases and did 3D reconstructions with MIP and VR using Vitrea software. These cases were later discussed in multidisciplinary teams that included radiologist, neurologist, neurosurgeon and interventional staff.

RESULTS

Of 210 patients, 118 (56%) were females and 92 (44%) were males, with an age range from 21 to 86-year-old. From a total of 244 aneurysms, the anterior communicating artery was the most frequent aneurysm location (33%), followed by middle cerebral artery (23%), the posterior communicating artery with 16% and internal carotid artery with 14%. Other localizations were found in less than 10% of cases (fig. 1). We also found 15 patients with multiple aneurysms.

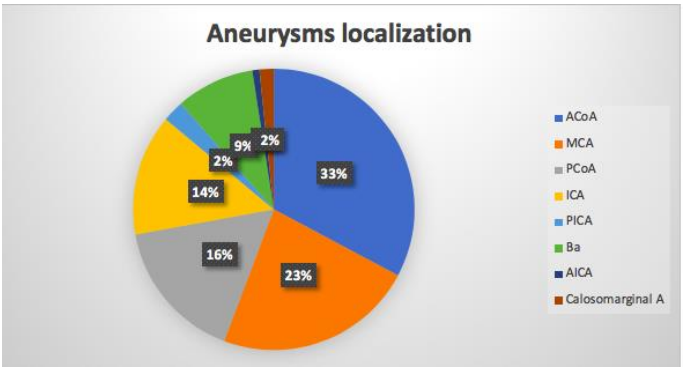

Fig 1. Aneurysms localization

The postprocessing techniques that are discussed in this article are MIP and VR which are most helpful in the diagnosis and assessment of intracranial aneurysms.

DISCUSSION

Although DSA remains the gold standard for diagnosis of intracranial aneurysms (4) even in recent studies (5), Willinsky *et al*. identified a rate of 1.3% neurologic complications in a number of 2,899 procedures with the mentioning that the patients had age-related vascular diseases (6). In another study with a more selected series of patients, Dawkins found a lower rate of complications, 0.34% in 2924 diagnostic procedures (7).

Wintermark *et al*. discovered a sensitivity of 94.8% of CTA in detecting intracranial aneurysms with scanners with 8 and 16 detectors but with the ongoing development of multi-slice imaging (8), Wang *et al*. found an overall sensitivity, specificity and accuracy of 3D CTA of 96.3, 100 and 94.6% of intracranial aneurysms using a 320-detector row scanner (9).

It is very important to go through all axial images before using the reconstructions, but the use of MIP or 3D VR afterward can improve the report by adding information about aneurysm morphology, size, orientation, neck and other aspects that neurosurgeons need for treatment planning.

In our study most aneurysms were found on anterior communicating artery, like in the Hwang *et al*. study (10).

In most studies was used 64-row spiral CT unit (11, 12, 13). In our study was used 32 slice CT unit.

Maximum intensity projection is a technique in which the brightest voxel from a volume of CT data is collected and therefor used to reconstruct an image (14). Therefore, it is not a 3D method, but it creates 2D images and depth information is lost (15). This technique can facilitated the view of arterial tree in an "angiographic" image and vascular particularities can be better displayed. It offers an easy visualization of small caliber intraparenchymal arteries in an enhancing organ, such as brain but also kidney, liver (16, 17) and it is very useful for the evaluation of arteries in potential living transplantation donors (18).But MIP reconstructions can be edited using only windowing parameters and not opacity, color or shading.

Regarding intracranial aneurysms, MIP reveals smaller vessel branches, and this makes it well suited for rapid evaluation of collateral vessels (17).

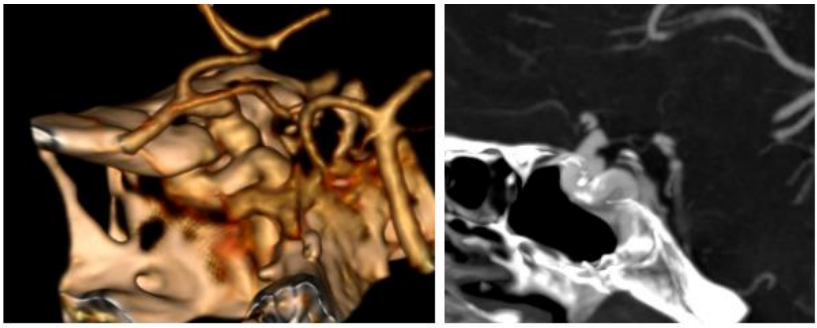
A limitation of the technique is represented by wall calcifications because the lumen of the vessel can be masked, and the stenosis overestimated (19) (fig. 2). Also, skull base has a higher attenuation than arteries and the disadvantage of this technique is that bone removal from the data set is necessary and it is a time-consuming task (20).

MIP is easy to use but it must be remembered that it uses only 10% of the information from the given volume.

MIP imaging of CTA has proven its usefulness in diagnosing cerebral vasospasm following subarachnoid hemorrhage in a study conducted by Kim *et al*. that compared the accuracy of MIP images of CTA with DSA. Therefore, the number of unnecessarily invasive DSA can be reduced (21).

Volume rendering is a technique used to visualize three-dimensional scalar fields so unlike MIP, VR maintains depth and spatial relationship (22). Ever since 1987, Fishman reported that VR is more useful than axial and 2D multi-planar reformatted images in assessing subtle acetabular fractures (23)

and later on, Levin *et al*. reported better evaluation of brain cortical lesions (24). VR is also useful for liver, knee, aorta imaging (25, 26).

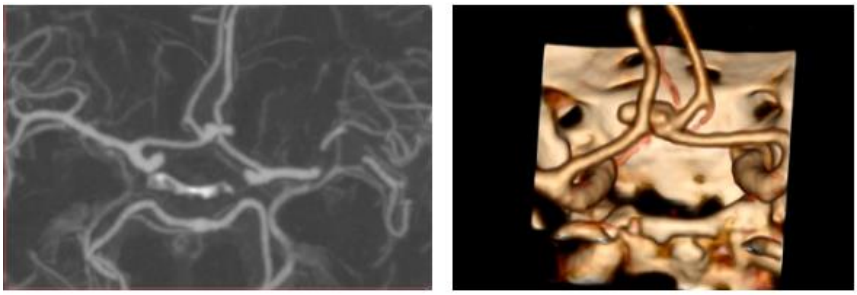


a b

Fig. 2. Another case is that of a 65-year-old woman with an internal carotid artery aneurysm. MIP reconstruction creates the vascular map, but the vessel lumen and wall calcifications cannot be individually defined (a). The volume rendering improves the visualization by enabling a color display with differentiation between lumen and calcification (b).

There are many software that can provide 3D reconstructions from CT data sets and almost all have similar interface and tools to edit the volumes. In this study we used Vitrea software 4.1.52 to obtain useful 3D reconstruction for neurosurgeons (fig. 3).

VRT shows vascular anatomy but also provides information about soft tissue, bone, muscle and other structures that can play an important role in a more comprehensive understanding of the pathology or surgical approach (fig. 4). Some parameters such as window width and level, opacity, brightness can be modified to depict more accurately the vasculature (19). This may also represent a challenge because adjusting these parameters is an interactive process that has an interobserver variability and is dependent of user's experience (27).



a b

Fig. 3. A 56-year-old patient with an anterior communicating artery saccular aneurysm, injected from right and oriented to the left. The aneurysm is better seen on MIP reconstruction in axial plane (a) but VR provides a better understanding of the morphology of the aneurysm (b).

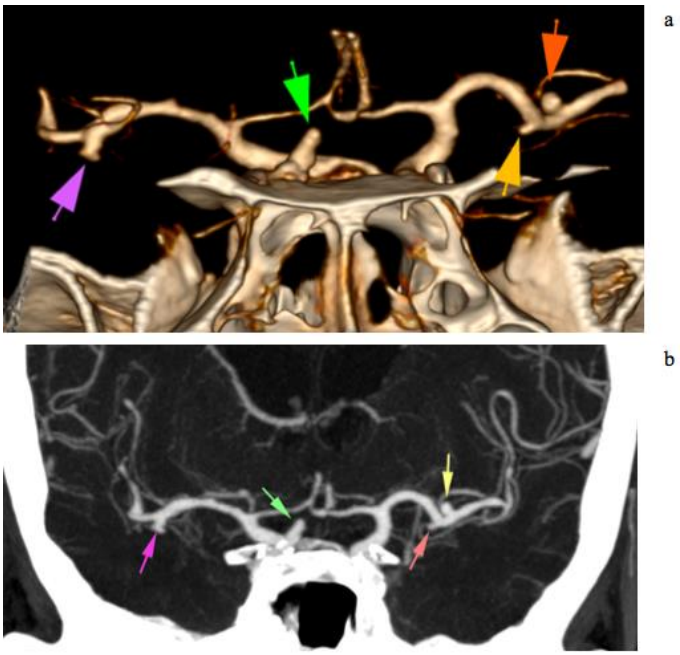


Fig. 4. A 48-year-old female patient with multiple aneurysms (two aneurysms on left MCA, one aneurysms on right MCA and one aneurysm on right PCoA). Volume rendering has the advantage of revealing all the aneurysms and rotate the 3D reconstruction in different planes (a) while MIP can display in full detail only one or two aneurysms, depending on the location of the aneurysmal dilatations (b).

Most software provide simple interface with user-friendly command icons in the left side of the screen and some also include a few preset functions for 3D VR. For example, after a region of interest is selected in the multiplanar reconstruction, when using Vitrea, we can select the Circle of Willis protocol and a 3D reconstruction will be made with only vessels present. A "bone" preset can be selected and the bone structure that is in the region of interest is added to the 3D model. Another benefit of VR is that the colors of the arteries and bones can be chosen to be distinctive and a better appreciation of the vessel direction within an osseous canal can be made. The software also has a knife tool that gives options to cut inside, cut outside and clear area in order to better edit the image. The user can also use this tool to remove the bone structure and make a simulation for a surgical approach.

Consequently, preoperative understanding of the anatomic individualities of each patient can be of major advantage in achieving a more precise and a less invasive approach. Furthermore, this may help with anticipating potential complications and intraoperative difficulties (28).

In another study, Jha *et al*. supports the use of VRT for training residents and in surgical planning of arterio-venous malformations, aneurysms, skull-base lesions, lesions of the brain and spine lesions (29).

Overall, many studies report that using VR is a very useful method to analyze vascular structure in detail, understand the

morphology, size, orientation of the neck of the aneurysm, the parent vessel, the emerging vessels and their direction and for choosing the treatment plan, either surgical or endovascular (30, 31).

In our experience, both reconstruction methods are useful, and we routinely use both in our practice but, because of its limitation, we would not use only MIP images without a correlation to volume-rendered images.

CONCLUSIONS

Postprocessing tools with 3D reconstructions should be used more often in neurosurgery because it enables a more comprehensive understanding of aneurysms, the morphologic details, complex anatomy of vascular structures and 3D relationships.

MYOCARDIAL ISCHEMIA AND COMPONENTS OF OXIDATIVE STRESS IN DIABETES - AN ACCIDENTAL ASSOCIATION? CASE REPORT AND LITERATURE REVIEW (Abstract): The global epidemic of diabetes can be alarming and extremely severe. Diabetes, especially in type 2 cells, is officially recognized as a major and independent cardiovascular risk factor. We are presenting the case of a 55-year-old female diabetic patient, with postoperative status, admitted to the internal medicine clinic for polymorphic symptomatology and elevated blood pressure values at home. From an evolutionary point of view, the patient presents electrocardiographic and enzymatic dynamics, and the therapeutic approach was non-interventional. This case was particular due to the postoperative status, cardiovascular risk factors and important prognostic implications through pain perception disorders. The assessment of the overall cardiovascular risk is important to determine the optimal time to initiate the therapy, its intensity, and therapeutic targets. The role of the multidisciplinary team is essential in the complex management of the patient. The aim of this paper is to make a brief review of the role that endothelial dysfunction and oxidative stress have in diabetes and cardiovascular disease. **Keywords:** ENDOTHELIAL DYSFUNCTION, OXIDATIVE STRESS, DIABETES, CARDIOVASCULAR DISEASE, THERAPEUTIC TARGET.

World Health Organization predicts that diabetes and coronary heart disease will remain the leading causes of death over the next two decades. Correct and early risk stratification is essential and decides the therapeutic management (1). Long-term monitoring of the coronary and diabetic patient should include lifestyle changes, correction of risk factors, and secondary prevention. Diabetes mellitus, a complex and multifactorial metabolic disorder, is characterized by hyperglycemia and the development of micro and macrovascular complications. One of the factors that contribute to the development of insulin resistance is oxidative stress. People with diabetes have a higher risk of silent myocardial ischemia and to develop myocardial

infarction compared to the non-diabetic population. Most often, myocardial ischemia is asymptomatic in diabetic patients (2).

There is a close relationship between oxidative stress, diabetes, and coronary heart disease. Diabetes increases the risk of cardiovascular disease. An early indicator of heart disease in diabetic patients is the endothelial dysfunction. The pathophysiological factors incriminated in the endothelial dysfunction in diabetes are dyslipidemia, inflammation, and oxidative stress.

Endothelial dysfunction, commonly associated with diabetes, is an early indicator of diabetic vascular disease, and the pathophysiological mechanism is complex (3). Current studies point out that diabetes, insulin resistance and atherosclerosis are common pathogenic mechanisms, and endothelial dysfunction could explain each of these pathological conditions. Metabolic syndrome, insulin resistance and hyperglycemia lead to damage to the vascular wall and the occurrence of cardiovascular events caused by oxidative stress, inflammation, platelet hyperactivity and endothelial dysfunction (4).

Decreased NO bioavailability can be caused by several factors such as: decreased production of endothelial nitric oxide synthase (eNOS), blocking the cofactors necessary for eNOS synthesis, subsequently causing degradation or inactivation of excess NO by reactive oxygen species. The main cause of decreased bioavailability of NO in cardiovascular disease is the increased production of reactive oxygen species, peroxide ion, superoxide, or peroxide free radicals (5). Cardiovascular risk factors (hyperglycemia, hypertension, dyslipidemia) contribute to oxidative stress and the development of endothelial dysfunction (fig. 1). Therefore, a number of profibrotic and cell growth factors are released, stimulating the proliferation of smooth muscle cells and the production of excess collagen, with the initiation of atheroma plaque formation. Consequently, there is arterial remodeling, increased intima-media thickness and decreased arterial distensibility, also called early arterial stiffening (6, 7).

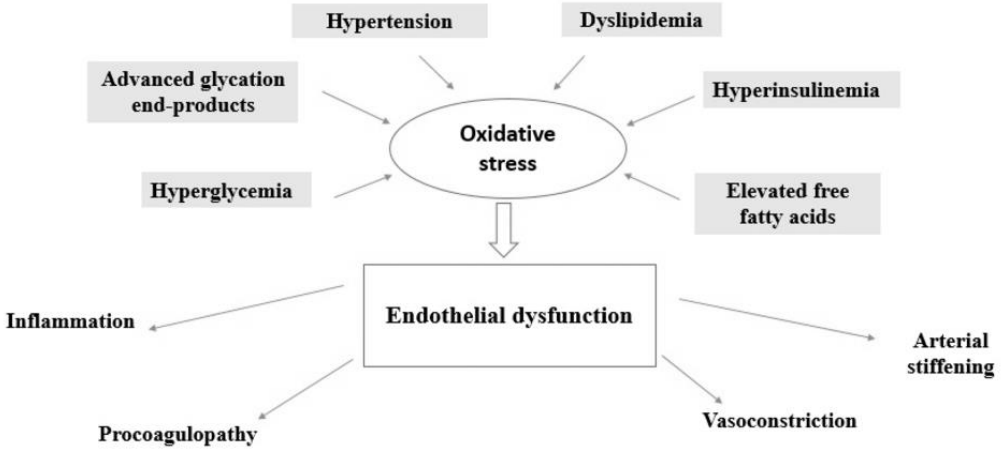

Fig. 1. Endothelial dysfunction in type 2 diabetes - consequences and pathogenesis. (adapted from Sandra J. Hamilton and Gerald F. Watts).

One of the pathophysiological mechanisms that lead to insulin resistance and diabetes is the oxidative stress. Under physiological conditions, pancreatic B-cells secrete and release insulin in response to increased postprandial blood glucose. Blood glucose is normalized by the penetration of glucose into the cell due to the increase in peripheral tissue expression of glucose transporters, especially GLUT 4 (8). But if the hyperglycemia is chronic, there is a chronic increase in insulin secretion that will cause the expression of GLUT 4 transporters to decrease, through a strong positive feedback mechanism. This is how insulin resistance appears. Reactive oxygen species (ROS) are implicated in the initiation and maintenance of insulin resistance (9).

CASE REPORT

The patient aged 55, from the urban area, is admitted in elective regime for: vertigo, physical asthenia, occipital headache, elevated blood pressure at home (self-monitoring systolic BP max = 180 mmHg, symptomatology with onset of about 3-4 days before presentation).

From the personal pathological history, we retain grade 3 essential hypertension (sBP max = 180 mmHg), type 2 diabetes mellitus treated with oral antidiabetic drugs, chronic venous insufficiency class C3 CEAP, endometrial adenocarcinoma for which total hysterectomy was performed, bilateral adnexectomy and lymphadenectomy approximately 30 days prior to the current presentation, grade I obesity. Perioperatively, the patient showed increased blood pressure (sBP max= 200 mmHg) and symptomatic episodes of sinus tachycardia (HR=120-130 beats/min). The patient is non-smoker, does not consume alcohol and the home treatment consists of a fixed combination of Olmesartan 40 mg / Amlodipine 10 mg, 1 cp/day, Metformin 1,000 mg 1cp/day.

At the objective physical examination, we note: the obese patient with BMI = 31.9 kg/m^2, malarial telangiectasis, postoperative sub-umbilical scar on the median line without inflammatory signs at this level, hyperemic conjunctiva, varicose inferior limbs bilaterally, rhythmic cardiac noise, BP = 250/80 mmHg, HR = 90 beats/min, bilateral pulsatile peripheral arteries, abdominal scar, increased abdominal volume on account of adipose tissue, without signs of peritoneal irritation.

From a biological point of view, on admission, the patient has hyperglycemia (fasting blood glucose = 135 mg/dL), liver dysfunction (SGPT = 74 U/L, SGOT = 39 U/L, GGT = 93 U/L), D-Dimer 0,968 µg/ml, TnT = 26,9 ng/L, CK = 143 U/L, CK-MB= 22 U/L, LDH = 244 U/L, Hb A1c = 6,8%, hypercholesterolemia (229 mg/dL), complete blood count, coagulation parameters and urine summary within normal limits. In order to exclude the diagnosis of secondary HBP, during hospitalization, additional investigations were performed: urinary catecholamine (adrenaline), vanillyl mandelic acid, cortisol, ACTH with results within the normal limits and quantitative proteinuria also with normal results.

Electrocardiogram on admission (fig. 2): sinus rhythm, intermediate QRS axis, HR = 83 beats/min, symmetrical wide negative T V_3-V_6.

We mention that the patient presented at admission an electrocardiogram performed postoperatively that showed a normal morphology in all derivations (fig. 3).

Chest X-ray showed normal lung transparency and heart within normal limits.

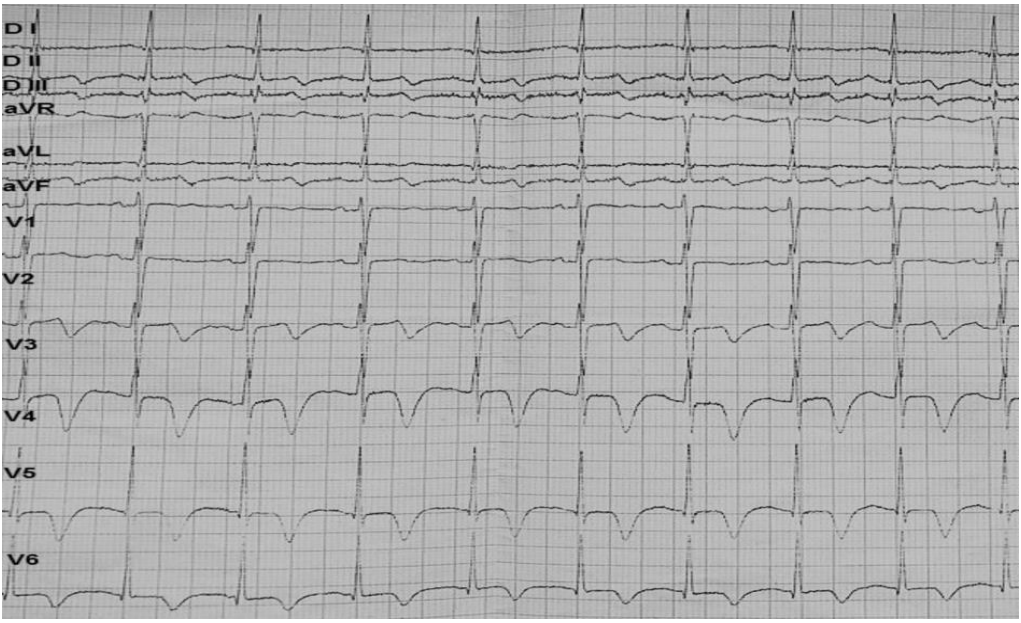

Fig. 2. Electrocardiogram on admission

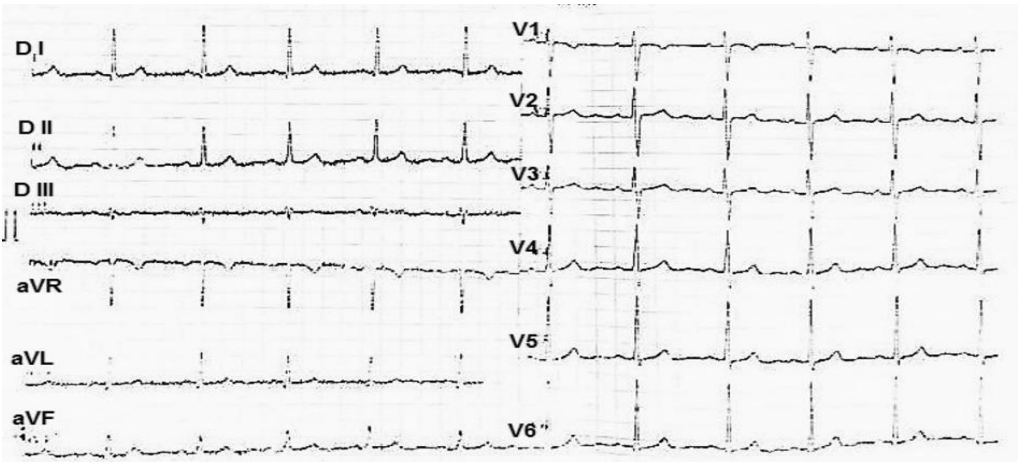

Fig. 3. Postoperative electrocardiogram

Abdominal-pelvic ultrasound reveals some infra-centimetric calculi at the cholecystic level and the post-surgical absence of the uterus and the annexes, without any further changes.

We can observe on the transthoracic echocardiography the left ventricular hypertrophy with preserved systolic function, apical hypokinesis at the 1/3 apical inferior wall and type I diastolic dysfunction delayed relaxation, without significant hemodynamic valvopathy, ejection fraction = 51%.

Vasodilator treatment with glycerol

trinitrate infusion solution, beta-blocker, angiotensin receptor blocker, dihydropyridine calcium blocker with progressive control of BP values was initiated. On the third day of hospitalization the patient discreetly manifested a myocardial cytolysis syndrome with remission on the following day; the electrocardiographic aspect is constant throughout the hospitalization. The particularity of the case: patient with postoperative status (radical gynecologic-oncologic intervention 30 days ago), known with diabetes mellitus controlled by oral antidiabetics, hypertensive, who is admitted for increased blood pressure manifested by headache and vertigo, an opportunity with which electrocardiographic (?) and via myocardial ischemia enzymatic turn in the absence of suggestive symptomatology and in the absence of coronary lesions.

DISCUSSION

Diabetes is a well-known risk factor for cardiovascular disease, doubling the risk of acute vascular events (coronary heart disease, ischemic stroke, and vascular death) independent of other risk factors. The relative and absolute risk is increased especially in women and young people, being higher in patients with a long evolution of diabetes, in those with poor control of glycemic values and in those with microvascular impairment (1). As diabetes progresses, it causes endothelial dysfunction and changes in energy metabolism leading to early atherosclerosis in the middle and large arteries affecting the coronary arteries.

The vascular endothelium is a complex organ, with an important metabolic, secretory, and immunological role, with auto- and paracrine function that thus provides a "first line" of defense against atherosclerosis (10, 11). It intervenes in the regulation of vascular tone, fibrin-coagulant balance, cell proliferation and inflammatory processes, being considered the main regulator of homeostasis of the vascular wall (12, 13). Damage to the vascular endothelium thus causes atherosclerosis and increases the risk of cardiovascular events (14, 15).

Endothelial dysfunction, defined as a reduction in the bioavailability of vasodilators, especially nitric oxide (NO) and an increase in vasoconstrictors, causes, along with structural and functional consequences, stiffness, and remodeling of the arterial wall. This is the link between the onset of atherosclerosis and cardiovascular risk factors (16). Endothelial dysfunction is initiated by oxidized LDL which influences the adhesion of monocytes and their migration into the subendothelial space, their transformation into macrophages and subsequently the formation of foam cells.

Insulin resistance and hyperinsulinemia play a particularly important role in endothelial dysfunction. Increased insulin levels resulting from insulin resistance activate the renin-angiotensin system as well as the sympathoadrenergic system which causes important metabolic, hemodynamic, and vascular changes, including endothelial dysfunction. Although, physiologically, insulin stimulates the production of nitric oxide by endothelial cells (by increasing the activity of nitric oxide synthetase by activating phosphatidylinositol-3 kinase) this action is reversed or decreased in patients with insulin resistance (17).

Another mechanism by which insulin resistance causes changes in the vascular endothelium is to increase the production of oxygen free radicals and the release of excess fatty acids from adipose tissue that eventually produce oxygen free radicals

that inhibit the production of NO (18).

Current studies highlight the role of insulin resistance and the initiation of inflammation, mainly the serum level of C-reactive protein. In the presence of C-reactive protein, LDL-cholesterol particles are taken up by macrophages and transformed into foam cells in the subendothelial space. Oxidation of LDL-cholesterol particles may increase protein levels that stimulate the endothelium to preferentially enhance ADMA production instead of NO (19, 20, 21).

Although the precise mechanism by which insulin resistance causes endothelial dysfunction remains a controversial topic and remains to be elucidated, in addition to the decreased response and nitric oxide synthesis, insulin resistance has been associated with increased endothelin 1 production, which may cause vasoconstriction, with a particularly important role in the development of hypertension. Endothelial dysfunction may also involve vasoconstrictor substances (endothelin 1 and angiotensin II) (22) and vasodilators such as the endothelium-derived hyperpolarizing factor (EDHF) and prostacyclin (23, 24, 25, 26).

Although so strongly involved in various pathological conditions, endothelial dysfunction is not yet fully investigated and used in medical practice, because for a long-time endothelium-dependent relaxation could not be documented in humans, and due to the complexity and adaptability of this phenomenon.

The symptoms of a patient with diabetes and acute myocardial ischemia are more often atypical. This may present as silent ischemia or with a variety of nonspecific symptoms. Silent myocardial ischemia is more common in the diabetic patient than in the general population and seems to be the main form of atypical presentation of both acute and chronic myocardial ischemia (2). The exact prevalence of myocardial ischemia remains unknown, but an analysis of data from the Framingham study shows in the group of asymptomatic patients with risk factors, 3% cardiovascular mortality (27).

The atypical symptomatology of acute myocardial infarction in diabetic patients is a subject under investigation in major clinical trials and the conclusions are diverse which makes definitive statements difficult (28). Autonomic neuropathy, disorders of the metaiodo-benzylguanidine metabolism, pain perception disorders through sympathetic denervation are some of the possible explanations for the atypical symptoms of myocardial ischemia in diabetic patients (29, 30, 31). In patients with diabetes, a resting electrocardiogram can identify silent myocardial infarction in 4% of cases, which is associated with an increased cardiovascular risk and increased all-cause mortality in men but not in women (32).

Another important factor that contributed to the atypical presentation of the patient was the post-surgical status. Despite optimal surgical and medical care, approximately one million patients worldwide die annually shortly after undergoing surgery. A major contributor to this postoperative mortality is “silent myocardial ischemic events“ which are often unrecognized. Routine assessment of cardiac biomarkers is an important step in identifying high-risk patients and improving perioperative care (33).

Major gynecological interventions (34) have an estimated intermediate risk (1-5%) of cardiovascular death and myocardial infarction at 30 days postoperatively. This risk only considers the surgery undergone without considering the patient's comorbid-

ities (35).

Another feature of this case is the absence of significant coronary changes. The absence of obstructive coronary artery disease in patients with signs of myocardial ischemia is a common clinical scenario that may be due to several mechanisms (epicardial coronary vasospasm, structural or functional changes of microcirculation). Due to the prognostic and therapeutic implications, the pathophysiological mechanism and a complete diagnosis must be followed. The intracoronary acetylcholine test or the adenosine test can evaluate the involvement of the epicardial coronary arteries as well as the endothelial dysfunction of the coronary microcirculation (36).

CONCLUSIONS

Diabetes is a huge public health problem that puts a lot of financial pressure on public health systems. It is the most common metabolic disorder that has a multifactorial etiology. Hyperglycemia and inadequate peripheral tissue response to insulin contribute to micro and macrovascular complications, which decrease quality of life and life expectancy. There is a close relationship between diabetes, oxidative stress, and endothelial dysfunction. Only understanding the pathophysiological mechanisms underlying the development of diabetes and knowing the risk factors can prevent the appearance of this condition and the development of complications.

ERCP-RELATED PERFORATIONS: COVERT OR OVERT ADVERSE EVENTS? A PROSPECTIVE CASE SERIES (Abstract): **Background** Perforations related to endoscopic retrograde cholangiopancreatography are a rare but feared adverse events, with significant morbidity and mortality. In order to describe the potential patient profiles related to post-ERCP perforations we present a case series of three patients, documenting several particular aspects related to their ERCP related complications. **Material and methods:** Between 01.01.2018 and 31.08.2020 a total of 403 patients underwent therapeutic ERCP in the tertiary medical center represented by "Sf. Spiridon" County Clinical Emergency Hospital, Iasi, Romania. Three duodenal and pancreaticobiliary perforations were identified (0.74%). **Results:** Three types of perforations (according to Stapfer *et al.*, 2000 classification) were described: type 2, type 3 and type 4. All patients presented patient-related risk factors and developed post-ERCP comorbidities that proved to be of significant impact to their prognosis resulting in two cases of fatal outcome. Given each case particularities, positive diagnosis was established using cross-sectional imaging. The therapeutical approach was complex and included surgical treatment, as advocated in current literature. **Conclusions:** Post-procedural diagnosis of perforations can prove to be challenging but an early diagnosis, an appropriate therapeutic approach and a well conducted post-procedural patient surveillance can significantly improve patient outcome. **Keywords**: ERCP, ADVERSE EVENTS, SURGERY, INFECTIONS.

Perforations represent a significant part of the possible complications related to upper gastrointestinal procedures, with an increased incidence among interventional endoscopic techniques (1). Both endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy have an overall complications-associated rate between 0.09% and 1.67% (2, 3) with duodenal perforations representing 0.08 % to 0.6% (4, 5, 6) or roughly one third of the total ERCP related perforations. What delineates them from other ERCP-associated complications are the high mortality rates ranging from 10% to 23% (6, 7, 8) making post-ERCP perforations the complication with the highest lethal outcome. However, the overall low incidence as well as the diversity in the risk factors lead to multiple epidemiological biases in the *evidence-*

based facts related to post-ERCP perforations.

Although perforations are known complications of ERCP for which endoscopic extended sphincterо-papillotomy and post papillotomy sphincteroplasty are well known risk factors, recent publications, including some guidelines, have shown that sphincteroplasty is characterized by a lower perforation risk than sphincter-papillotomy (6, 9, 10, 11). In order to describe the potential patient profiles related to post-ERCP perforations and due to the relatively lesser frequency of such complications, we aimed to present a case series of three patients, documenting several particular aspects related to their ERCP related complications.

MATERIAL AND METHODS

Patients

A prospective study was conducted that included 403 patients who underwent therapeutic ERCP from 01.01.2018 to 31.08.2018 in the tertiary medical center represented by *Saint Spiridon* Emergency Hospital, Iasi, Romania. Three post-ERCP perforations were identified and classified defined according to Stapfer *et al.*, 2000 classification (tab. I). Only duodenal and pancreaticobiliary perforations were detected within the study cohort.

TABLE I

Classification of post-ERCP perforation after Stapfer *et al.*, 2000

Perforation	Type 1: Lateral or medial duodenal wall perforation, endoscope related
	Type 2: Periampullary perforations, sphincterotomy related
	Type 3: Ductal or pancreatic perforations due to endoscopic instruments
	Type 4: Due to excess compression of air in the duodenum with presence of retroperitoneal air

From the total patients reviewed (tab. II) 19.1% presented post-ERCP complications, most of which were of infectious nature (8.93%). Acute pancreatitis occurred in 8.68% of the cases, post-ERCP hemorrhage in 2.98% and perforation in 0.74% of the cases with significant low incidence compared to other ERCP related complications.

TABLE II

Post-ERCP complications in the conducted study

Procedure ERCP (n=403)	Complications	Pancreatitis	Hemorrhage	Infection	Perforation
N	77	35	12	36	3
%	19.11%	8.68%	2.98%	8.93%	0.74%

In the conducted study three cases of post-ERCP perforation were identified, representing 0.74% of the total patients. Given the impossible task of carrying out an univariate study assessing the problems associated with this type of complication, we will present the case-studies of the three patients analyzing the evolution of their clinical and paraclinical status.

CASE PRESENTATIONS

I. First case C. E.

The first case involves a 27 years-old female patient, referred from the surgical department for biliary stones extraction. She experienced recurrent 48-72 hours

history of right upper quadrant colic pain, and altered blood works suggestive for biliary obstruction, without jaundice. The abdominal ultrasound and CT scan prior to the procedure revealed multiple gallstones less than 1 cm in diameter in the gallbladder and in the common bile duct (CBD) with CBD dilated up to 8 mm and biliary radicles dilated up to 3 mm. The patient consented to the procedure and elective ERCP was performed.

During the procedure, a modified papillary anatomy with a small infundibulum (type 2) papilla was identified, the cannulation proved to be difficult and required free-hand *needle knife precut* sphincterotomy.

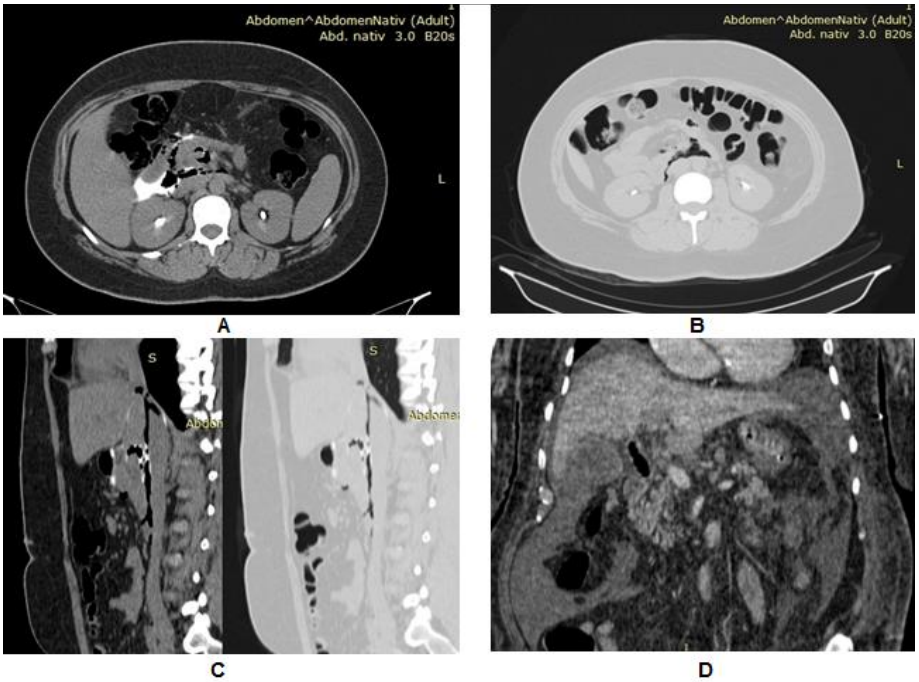

Fig. 1. CT scan images recovered from the C. E. case

Within the 24 hours evaluation following the procedure, the patient presented altered clinical status with tachycardia, tachypnea, tenderness in the right upper quadrant, dorsal thoracic pain, nausea and absence of bowel movements with a qSOFA score of 1. Blood panel showed systemic inflammatory response syndrome (SIRS) elements, with persistent elevation of C-reactive protein (CRP) from 0.89 mg/dL to 3.56 mg/dL. Given the clinical progression of the patient, a second emergent thoraco-abdominal computed tomography (CT) scan was performed, showing ERCP-injected contrast outside the biliary tract and gas bubbles in the retroperitoneum (fig. 1. Section A: axial section CT scan without contrast of the inferior part of the duodenum). There were also air bubbles surrounding the aorta and inferior vena cava, (fig. 1. Section B: axial section CT scan without contrast of the of the renal hilum using the lung window), with air dissecting through the retroperitoneal compartments tracking the inferior vena cava (fig. 1. Sec-

tion C: sagittal section abdominal CT scan without contrast). Fluid collections containing a mixture of hydro soluble contrast substance and air bubbles were present in the hepatic hilum, tracking the hepatoduodenal and pericaval ligaments.

A diagnosis of type 2 post-ERCP perforation was established. The patient underwent classic laparotomy with retroperitoneal approach, drainage and duodenal juxtapapillary suture. Also, cholecystectomy was performed with biliary-digestive and choledochal-duodenal anastomosis. After the surgery, the patient presented gradually favorable clinical course and was discharged after 22 days of hospitalization. She maintained a favorable clinical and paraclinical outcome at the 60 days follow-up.

II. Second case C. V.

The second case involved an 82 years-old male, admitted to the gastroenterology department for common bile duct stones associated with jaundice, acute cholangitis and acute biliary pancreatitis, and as a result an emergency ERCP was arranged in the endoscopy unit. The diagnosis was established based on clinical, biological and imagistic features including abdominal ultrasound and emergency abdominal CT scan. Prior to the procedure the patient presented poor clinical status, with an ASA score of 4.

The procedure revealed modified papillary anatomy with a hooded (type 3) papilla and the presence of a juxtapapillary duodenal diverticula. A total of 8 standard guidewire cannulation attempts were made lasting 6 minutes, followed by *needle knife* fistulotomy and successful CBD cannulation. The diagnosis cholangiogram confirmed multiple gallstones, the largest one measuring 15 mm and CBD diameter discreetly exceeding it. Sphincteroplasty was performed with a 13-15-18 mm controlled radial expansion balloon (CRE) and using an extraction balloon 4 stones were retrieved measuring 10 to 15 mm.

On the 24-hour evaluation post-ERCP the patient presented stable hemodynamic status, was conscious but somnolent, physical exam disclosed tachycardia and tachypnea with a qSOFA score of 3. Clinical examination of the abdomen remained inconclusive. Laboratory studies revealed improvement in the cholestatic syndrome, decreasing levels of the total bilirubin and cholestatic enzymes but with the presence of SIRS parameters, rising levels of CRP from 11.27 mg/dL to 32.18 mg/dL and acute renal failure with elevated serum creatinine from 1.07 mg/dL to 3.2 mg/dL. Also, high levels of sepsis markers were identified, with a presepsin value of 12,038 pg/mL. Blood cultures were collected with prior broad spectrum antibiotherapy from the admission with 3rd generation cephalosporin, isolating *Pseudomonas aeruginosa* with extended antibiotic resistance pattern, susceptible only to Amikacin and Colistin. An emergent abdominal CT scan was performed showing a moderate-density radiopaque image located in the Vater ampulla and an upstream dilated CBD suggestive for residual lithiasis (fig. 2. Section A: axial and coronal section abdominal CT scan without contrast). There was also bilateral portal branch thrombosis (red arrow) with rim contrast enhancement of the vessel wall suggestive for pylephlebitis (blue arrow), small gas bubbles surrounding the choledochal (yellow arrows) and peripheral hypoattenuating areas indicating perfusion abnormalities (fig. 2. Section B: post-contrast injection, central venous phase of the liver). Diagnoses of type 4 post-ERCP perforation and severe acute post-ERCP cholangitis were established.

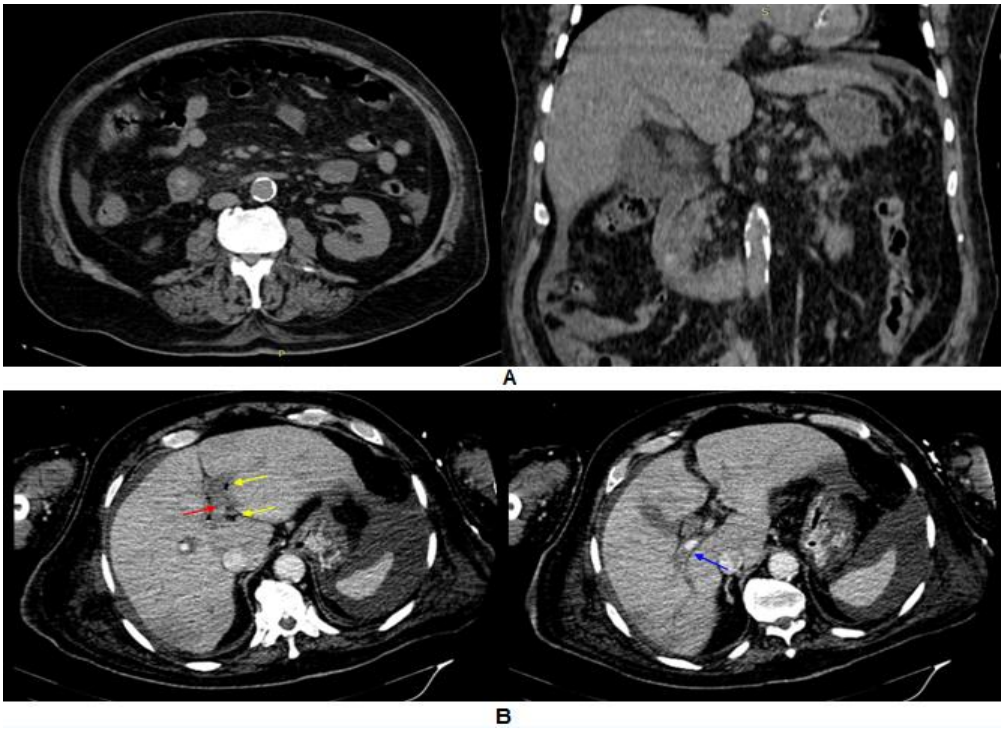

Fig. 2. Emergency CT scan images recovered from the C. V. case

The patient was admitted into the Intensive Care Unit (ICU). Exploratory laparotomy was performed with external abdominal transmural biliary drainage, gastrojejunostomy, a jejunal feeding tube was placed and the peritoneal and retroperitoneal cavities were drained. Postoperatively, the patient's functional status progressively declined, and he subsequently passed away due to multiple organ failure and septic shock.

III. Third case P. E.

The third case is of a 54 years-old female patient, with no significant personal medical history except some infrequent dyspeptic symptoms. She was referred from the surgical department for biliary obstruction and jaundice, given that prior to her admittance an elective abdominal ultrasound showed dilated intra and extrahepatic bile ducts, a 12 mm CBD with no apparent obstruction and no cholecystolithiasis. Tumoral markers assessment revealed a CA19-9 of 12,000 U/L and subsequently an abdominal CT scan was performed given the high suspicion for a cephalic pancreatic tumor.

During the procedure there was modified papillary anatomy with no infundibulum (type 1) papilla resulting in a difficult cannulation and after bile duct cannulation the cholangiogram revealed distal Bismuth type 1 biliary stenosis measuring 2-3 cm, with macroscopic irregular surface suggestive of malignancy. On the attending physician's recommendation only bile duct brushing for cytology was performed and the patient was scheduled for pancreaticoduodenectomy. Shortly after the proce-

dure the patient maintained a favorable clinical state, however, 24 hours after ERCP she developed subcutaneous emphysema located on the chest, in the supra and sub clavicular fossae and the CT scan revealed dilatation of the biliary tree, with absence of filling in the distal part of the CBD, important asymmetrical mural thickening and contrast enhancement (red arrow) corresponding to a malignant lesion. (fig. 3. Section A: abdominal CT scan of the liver in portal venous phase). CT findings included procedure injected contrast extravasation around the gallbladder with free gas bubbles in the retro pancreatic, right peri-renal and para-renal areas extending to the mediastinum, with emphysema of the soft tissue in the right hemiabdomen and bilateral pleural effusion (fig. 3. Section B: post-procedural abdominal CT scan without contrast using lung and abdomen windows).

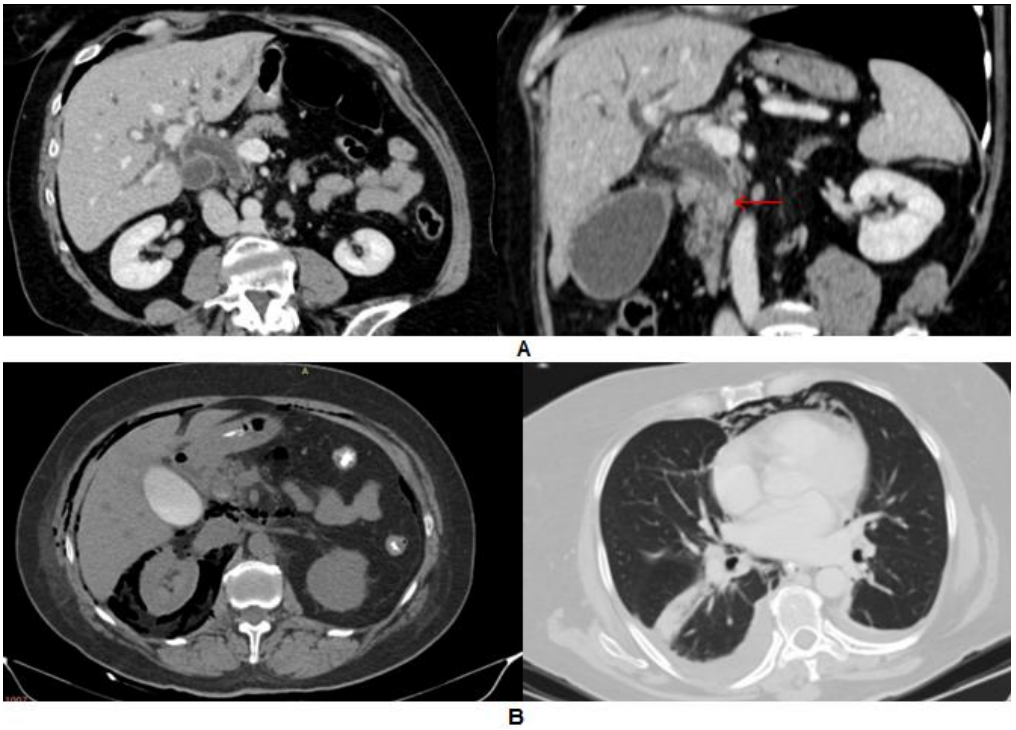

Fig. 3. Emergency CT scan images recovered from the P. E. case

Laboratory findings at the 24-hour evaluation included SIRS elements with elevated white blood cells 23,000/mmc, a CRP value of 13 mg/dL, aggravating cholestatic syndrome, a total bilirubin of 6.78 mg/dl (conjugated bilirubin 5.2 mg/dL) and elevated sepsis markers, with a presepsin value of 6,870 pg/dL. A diagnosis of type 3 perforation was established, with pneumoperitoneum, pneumomediastinum, subcutaneous emphysema, and severe acute post-ERCP cholangitis given the underlying malignant biliary stenosis. Blood cultures were collected. The patient received antibiotherapy with Piperacillin - Tazobactam and Amikacin, followed at 32 hours

post ERCP by acute renal failure onset, with serum creatinine of 5.8 mg/dL forcing discontinuation of Amikacin administration.

The patient underwent emergency laparotomy with cholecystectomy, external trans cystic biliary drainage, drainage of the retroperitoneal and peritoneal cavities and gastrojejunostomy. Bile samples were collected for culture. After the procedure, the patient showed signs of septic shock, with impaired hemodynamic function requiring two vasopressors. The blood and bile cultures isolated multidrug-resistant *Pseudomonas aeruginosa* susceptible only to Colistin and Amikacin. Histological examination of the endoscopic tissue sample was suggestive of malignancy showing high atypical mitoses. Despite the maximum multi-organic support, the patient passed away 3 days after the surgical intervention.

DISCUSSION

All three cases presented patient-related risk factors such as female gender (cases I and III), older age (case II), as well as procedure-related risk factors such as difficult cannulation and needle knife precut access papillotomy (cases I and II); balloon sphincteroplasty and bile duct brushing (cases II and III). The contribution of each procedure-related factor is relatively difficult to be quantified given the low incidence rate of 1% reported in the literature (6, 12, 13) for such adverse events. Such complication rates are similar to those described in our cohort. One common aspect of the three cases is represented by the difficulty in establishing a positive intraprocedural diagnosis, understandable given the small perforation size (for cases I and II) and the choledochal localization due to the underlying tumor (case III). For all the three cases demonstration of perforation was established using cross-sectional imaging that showed free extra-digestive air (pneumorethroperitoneum, pneumomediastinum, subcutaneous emphysema), and for cases II and III descriptive elements of severe acute cholangitis and hepatic abscesses. For the complications that occurred in cases I and III, acute post-ERCP cholangitis proved to be a comorbidity with significant impact. Another common feature was that all patients underwent surgical treatment, as advocated in current literature. Such decision was based on the experience of our tertiary center and on the patient's overall course following the perforation (6, 13, 14).

Post-procedural diagnosis of perforations can prove to be challenging as there are no specific symptoms. Therefore, very frequently such complications are considered to be covert. Epigastric pain radiating to the back is the most common finding, without being reliable given it's attribution to acute secondary pancreatitis, but often progressing to an acute abdomen accompanied by severe systemic inflammatory response (3, 13). Presence of subcutaneous emphysema gives a high index of suspicion for perforation whereas pain and systemic inflammatory response are a common find in the first 12 hours after the procedure (6). Signs and symptoms of peritonitis develop in first 4-6 hours post ERCP leading to shock if not promptly managed (6, 15). Moreover, in peri-ampullary perforations the diagnosis may be delayed if there are elevated enzymes levels wrongly attributed to acute pancreatitis (16) which is a frequent comorbidity. Contrast-enhanced computed tomography is the diagnostic imaging method of choice for detecting the presence of free air of contrast material in

the peritoneal or retroperitoneal cavities, regardless of the injury (16).

To what extent anatomy of the papilla is relevant to the occurrence of perforative adverse events is questionable. Nevertheless, as stated by our study protocol we implemented a four types of classification system of the macroscopic appearance of the papilla that seems to influence the overall complication rates after ERCP (17).

CONCLUSIONS

Among the ERCP-related complications, perforations represent adverse events that do not solely involve the level of technical endoscopic skills, but also require the ability to achieve an early diagnosis, to establish an appropriate therapeutic approach and a well conducted post-procedural patient surveillance. Given that this type of adverse events usually precedes or is linked to infections or post-procedural hemorrhages their impact on overall post-ERCP mortality is high, with important subsequent potential implications on liability and malpractice.

ETHICAL APPROVAL

The research project, the motivation, objectives, and research methodology have been reviewed and approved by the "Grigore T. Popa" University of Medicine and Pharmacy of Iasi Board of Ethics. The subjects in this case report have given their informed consent to publish their cases along with the ERCP consent. In some cases, the consent for the interventional procedure was acquired from the closest legal representative, when emergent medical intervention was required, and the patient's status temporarily prevented them from giving their consent.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

NEWS

DEMENTIA - ROLE OF MAGNETIC RESONANCE IMAGING

The role of neuroimaging in dementia extends beyond its traditional role of excluding neurosurgical lesions. Neuroimaging contributes to the early diagnosis (which allows early treatment) of neurodegenerative diseases (Alzheimer's disease), recognizes pre-dementia conditions (mild cognitive impairment), assesses disease progression and is adopted in current trials investigating these diseases. The coronal images show the hippocampus, the main structure involved in many forms of dementia. Magnetic resonance protocol includes: coronal-oblique T1-weighted images (used for the assessment of medial temporal lobe and hippocampal atrophy), obtained in a plane orthogonal to the long axis of the hippocampus, parallel to the brainstem; sagittal reconstructions will enable the assessment of midline structures, parietal atrophy, which may be involved in certain neurodegenerative disorders; FLAIR images assess global cortical atrophy, vascular white matter hyperintensities and infarctions; T2-weighted images evaluate lacunar infarctions in the thalamus and basal ganglia, which can be missed on FLAIR images; T2*-weighted images detect microbleeds in amyloid angiopathy, depict calcifications and iron deposition; diffusion weighted image (DWI) is a supplemental sequence used for young patients or in rapidly progressive neurodegenerative disorders (for differential diagnosis with vasculitis) (Barkhof F, Hazewinkel M, Binnewijzend M, Smithuis R. Dementia - Role of MRI. https://radiologyassistant.nl/neuro radiology/dementia/role-of-mri).

MULTIDISCIPLINARY MANAGEMENT OF OVARIAN TUMORS IN CHILDREN AND TEENS - A RETROSPECTIVE STUDY

MULTIDISCIPLINARY MANAGEMENT OF OVARIAN TUMORS IN CHILDREN AND TEENS - A RETROSPECTIVE STUDY (Abstract): Ovarian tumors are the main pathology in the genital area among children and teens, their proper management remains a challenge due to the need for a multidisciplinary approach. **Aim:** The aim of the study was to evaluate the multidisciplinary management of ovarian masses in two reference centers. **Material and methods:** Files of patients, aged between 0-18 years, diagnosed with an ovarian tumor that required hospitalization between 2008 and 2019, were analyzed retrospectively. The following data were evaluated: demographic aspects, clinical symptoms, used imaging methods, tumor markers, type of treatment, presence of complications and their management, as well as the histological outcomes. **Results**: The study was performed on 803 patients with a mean age of 13.45 ± 4.06 years. 339 patients (42.21%) required surgery for tumoral pathology, this being most frequently located in the right side in 521 patients (65%). This surgical treatment was performed by laparoscopy in 55 of the operative cases (16.36%). The main symptom is abdominal pain, 85.42% of diagnosed patients being postmenarch. The most important complication is torsion, found in 22.12% of all ovarian tumors. The primary surgical intervention was cystectomy, which was performed in 53.09% of all surgical cases, in benign pathology, adnexectomy or oophorectomy being preferred in the case of complications or malignant tumors, the latter representing 17.69%. Regarding the histological results, 58.99% were serous cysts, and the main histological type among malignant tumors was represented by dysgerminoma 9.14%. **Conclusions**: Ovarian tumors in the analyzed age category are mostly benign, being more common in post menarche. The symptoms are nonspecific, dominated by pain in the lower abdominal floor, and the main complication is adnexal torsion. Preservation of fertility is the main goal in the management of ovarian tumors, conservative surgery with ovarian preservation being the main therapeutic concern. **Keywords**: CHILD, OVARIAN TUMORS, TORSION, TUMOR MARKERS, ADNEXAL, MASS, CYSTECTOMY, FERTILITY.

Ovarian tumors are the main pathology of the genital area among the infant population, their characteristics being different from those present in the adult population.

The annual incidence of ovarian tumors is 2.2-2.4 / 100,000 (1). Surgery among this population is also rare with a global incidence of 2.6 / 100,000 (2). Ovarian tumors range from simple serous cysts to malignant tumors, the latter accounting for 10-20 % of cases (3, 4). The incidence of malignant tumors is 0.102 / 100,000 in children under the age of 9 years and 1,072/ 100,000 respectively for the age group 10-19 years, observing an increase in the incidence with age (5), malignant pathology representing 60-70% among gynecological cancers present in this age category (6). The vast majority of ovarian tumors are benign and self-limited, surgical treatment is necessary only in complicated cases (7). Torsion is the main complication of these ovarian mases, especially due to the anatomical particularity represented by the presence of a longer ovarian pedicle compared to the adult population (8). Ovarian tumors in children are a challenge both from a diagnostic and therapeutic point of view, at this age group it is essential to preserve fertility and so a detailed analysis of the preoperative characteristics of tumors is necessary. In the case of benign tumors, it is recommended to excise them with the preservation as much as possible of functional ovarian tissue, in the case of neoplasia with an increased risk of malignancy ovariectomy is most often preferred (9). Minimally invasive surgery has become the gold standard in the treatment of benign ovarian tumors in the last decade due to the short recovery time, minimal pain (especially difficult to manage in children) and last but not least, the aesthetic aspect (10, 11). Signs and symptoms are most often nonspecific, mimicking multiple abdominal-pelvic medical or surgical pathologies (12). The aim of the study was to evaluate the multidisciplinary approach of ovarian masses and to compare the obtained surgical results with those in the literature.

MATERIAL AND METHODS

The study was carried out in two reference centers involved in the management of ovarian tumors, the "Sf. Maria" Clinical Emergency Children's Hospital, Iasi and the "Cuza-Vodă" Clinical Hospital of Obstetrics and Gynecology Iasi and included 803 patients (children and teens), under 18 years, diagnosed with ovarian tumors during the 2008-2019 period, from which complete data could be obtained. From this group, 339 patients required surgery, the remaining 464 patients benefited from conservative management. Being two regional centers, the study group also included patients addressed from the neighboring areas for adequate treatment. The patient files/electronic databases, the operating protocols and the histological results were analyzed retrospectively, being collected by the investigators involved the following data: demographic aspects (age, environment of origin, weight, height), clinical symptomatology, laboratory analyzes / tumor markers, imaging used in diagnosing tumoral pathology, type of treatment (conservative or surgical), tumor characteristics (location, uni/bilateral, size), case evolution, the presence of complications and their management and histopathological aspects. Patients with simple cysts, with a diameter < 5 cm were treated conservatively, recommending imaging reassessment at 6 months, while in the case of those with tumors with a diameter ≥ 5 cm, complex structure or clinical signs of acute abdomen, surgical treatment was performed. Patients with signs of acute abdomen benefited from emergency surgery, and in the

case of stable hemodynamics, elective interventions were performed. Regarding preoperative evaluation, patients requiring emergency surgery were clinically and paraclinically evaluated according to specific protocols, including complete blood count, coagulogram, inflammatory tests, beta HCG and ultrasound examination. In the case of patients who received elective surgical treatment, determinations of tumor markers (β HCG, AFP, CEA, Ca-125) were performed preoperatively as well as additional imaging evaluations by computed tomography / MRI, especially in situations where malignant tumors have been suspected. Although specific assessment of ovarian masses imaging by CT or MRI is higher compared to ultrasound (to distinguish signs of malignancy), these investigations were performed only in 26 cases (5.4% of surgical cases) due to reduced accessibility during the on-call shifts. The exclusion criteria were represented by the cases with incomplete documentation and those in which the intraoperative exploration revealed the presence of a pathology other than the initially considered ovarian tumor. The study was developed and conducted in accordance with the guidelines of the Helsinki Declaration, and approved by the ethics committees of the 2 centers. The rights of all patients included in the study were respected. Statistical analysis was performed using *SPSS version 17.0*, and data was analyzed for frequency by descriptive analysis and expressed as mean ± SD. Categorical variables were expressed as number and percentage of patients.

RESULTS

Analysis of demographic basic characteristic features of the patients included in the study revealed a mean age of 13.45 ± 4.06 years, an asymmetry was observed of the right and a right-tilted distribution, which means a higher frequency of this condition in teens over 13 years of age and in newborns (fig. 1). The examined patients had weights between 1.7 kg and 82 kg with an average of 42.87 kg. There is a preponderance of patients from rural areas, respectively 540 cases (67.24%), compared to those living in urban areas, 263 cases (32.75 %).

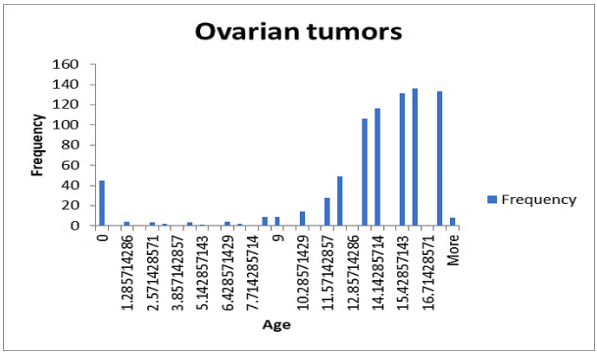

Fig. 1. Age distributes of the tumor pathology in the study group.

Regarding the site of tumor, they were highlighted especially on the right side (65%), in 11% of cases being bilateral. 85.42% of patients were diagnosed in postmenarche. Of the total number of patients enrolled in the study, only 42.21% required

surgery for the pathology, the rest benefiting from conservative management. Surgical treatment was performed by classical approach in most cases (83.77%), and in terms of complications of ovarian tumors, the most important one was torsion, present in 75 cases that required surgery (22.12%) (tab. I).

TABLE I

Integrated analysis of ovarian tumors in terms of location, diagnosis in relation to menarche, type of treatment performed and complications

Characteristics		Number	Percent
Location	Right	521	65%
	Left	192	24%
	Bilateral	90	11%
Menarche	Pre-menarche	117	14.57%
	Post-menarche	686	85.42%
Treatment	Surgical	339	42.21%
	Laparotomy	284	83.77%
	Laparoscopy	55	16.36%
	Conservative	464	57.78%
Complications	Torsion	75 (339)	22.12%

In patients who required surgical treatment, different interventions were performed depending on the symptoms, suspected malignancy or the presence of complications. The most frequent intervention was represented by cystectomy (53.09 %), followed by adnexectomy and oophorectomy (30.97%), adnexal detorsion saving the ovary was possible in a relatively small number of cases (11.19 %) (tab. II).

TABLE II

The types of surgery used in patients with ovarian tumors in the study group

Surgical procedure	Number	Percentage (%)
Detorsion - cystectomy	30	8.84%
Detorsion - fixation of the ovary	8	2.35%
Cystectomy	180	53.09%
Exhaust puncture	16	4.71%
Adnexectomy	56	16.51%
Ovariectomy	49	14.45%

In the case of ovarian torsion (75 cases), pelvic ultrasound was performed preoperatively in 48 cases (64 %) that showed loss or reduction of ovarian vascularization and which was later confirmed intraoperatively. In the remaining 24 cases (36%) it was not possible to perform imaging investigations due to hemodynamic instability, requiring emergency surgery, the diagnosis of torsion being confirmed intraoperatively. In case of torsioned tumors, the average age of the patients was 8.43 years old for benign tumors, respectively 7.25 years old for malignant tumors. Adnexal detorsioning to its

preservation was performed in 33 cases (44%), adnexectomy carried out in 16 cases (21.33%), while in the remaining 26 cases (34.66%) the removal of the ovary was necessary, without revascularization following detorsion. This complication was found in 8 cases with malignant pathology (10.66% of all twisted tumors), the remaining 89.33% being benign (tab. III).

Regarding the histological types, 57 surgically treated patients had malignant pathology (16.81%), representing dysgerminomas in 31 cases (9.14%), immature teratomas in 14 cases (4.12%), adenocarcinomas in 10 cases (2.94%) and 2 case of stromal tumors (0.58%). Benign tumors are represented by simple serous cyst in 200 cases (58.99%), necrotic ovarian tissue in 50 cases (14.74%) and mature teratoma in 29 cases (8.55%) (tab. IV).

TABLE III

Integrated analysis of the 75 cases with ovarian torsion in terms of location, diagnosis in relation to menarche, the type of treatment performed and the histological type

Characteristics		Number n / 75	Percent
Topography	Right	51	68%
	Left	24	32%
Menarche	Pre-menarche	39	52%
	Post-menarche	36	48%
Procedure	Adnexectomy / oophorectomy	37	49.33%
	Detorsion - fixation	8	10.66%
	Detorsion - Cystectomy	30	40%
Histology	Simple serous cyst	33	44%
	Necrotic tissue	30	40%
	Mature Teratoma	6	8%
	Dysgerminoma	5	6.66%
	Carcinoma	1	1.33%
	Borderline	1	1.33%

TABLE IV

Histological profile of ovarian tumors that required surgery (339 cases)

Histology		Number	Percent
Benign	Simple serous cyst	200	58.99%
	Necrotic ovarian tissue	50	14.74%
	Mature teratoma	29	8.55%
Malignant	Dysgerminoma	31	9.14%
	Immature teratoma	14	4.12%
	Adenocarcinoma	10	2.94%
	Stromal tumors	2	0.58%
Borderline tumors		3	0.88%

Conservative surgery represented by cystectomy was performed in 185 patients with benign pathologies, in malignant tumors preferring excision of the adnexa. Among the tested tumor markers, AFP had a specificity of 78%, while the specificity of β-HCG was 89%. Malignant tumors represented 17.69%, borderline tumors representing < 1%. The mean age for malignant tumors is 13.77 years ± 4.6 years, while for benign ones the mean age decreases to 12.59 ± 4.9 years. Conservative management of ovarian tumors was used in 464 cases (57.78%), with a mean length of hospital stay of 6.3 days. Clinical-paraclinical monitoring was accompanied in such cases by symptomatic treatment with analgesics, non-steroidal anti-inflammatory drugs, antipyretics and antibiotics. 48 cases that were initially managed conservatively, needed to be rehospitalized in an interval between 3-9 months and subsequently underwent surgery due to the size of the tumor and the symptoms, being included in the group of patients who needed surgical treatment. The most common symptoms of ovarian tumors were diffuse or localized abdominal pain (82.6%), nausea / vomiting (29.3%), palpable tumoral mass (19.3%), low-grade fever/fever (12.3%), intestinal transit disorders (11.6%), amenorrhea (3.4%) and vaginal bleeding (3.1%).

DISCUSSION

Ovarian tumors among children and teens are most commonly a benign pathology, which regresses after drug treatment, surgery being necessary in less than half of the cases, a situation highlighted in our study. The main symptom for presentation is pain in the lower abdomen, fact supported by other studies such as the study performed on 266 cases by How *et al.* or I. Banli-Cesur *et al.* on 146 cases (13). Numerous studies claim that transit disorders and the perception of a palpable abdominal mass are associated with an increased risk of malignancy, so the presence of one of these findings justifies an additional assessment (4, 11, 14, 15). Virilization and early puberty may be present in malignant tumors, and sex cord stromal ovarian tumors may secrete estrogen, androgens, or corticosteroids with specific clinical and paraclinical changes (14, 16, 17). Thus, in the presence of a palpable ovarian mass accompanied by signs of hyperandrogenism or hyperestrogenism, the suspicion of a malignant tumor of stromal origin arises. A predominance of tumor masses on the right side is observed in our study, which predisposes to an increased rate of torsion-type complications on this side. The torsion occurs when the ovary twists around its own ligaments, stopping the blood flow that served the ovary. Preoperative diagnosis is a challenge among the pediatric population, with acute pain requiring a complex differential diagnosis (18). Thus, pain located in the right iliac fossa can be associated with acute appendicitis, delaying diagnosis and surgical treatment, resulting in devascularization of ovarian tissue, with its necrosis, making it impossible to preserve it, reflected in the relatively high incidence of adnexectomies highlighted by us.

Also taken into account the role of the sigmoid located on the left side, could play a "protective" role against torsion. The rate of this complication was 42% in the study led by Cass *et al*, 10% in the study of Liu *et al.* and 23.5% in that of I. Banli-Cesur *et al.* (13, 18). In our case the torsion was present

in 22.12% of the cases. The use of ultrasonography, computed tomography or magnetic resonance imaging are implemented in clinical practice as diagnostic imaging methods, complementing each other provided they are accessible, which was not possible in all cases in our study (19).

Ultrasonography is, however, the main imaging method used in the diagnosis of ovarian tumors, especially in an emergency, as well as possible complications. Due to the accessibility and non-invasiveness of the method, it is the main tool in assessing the topography and vascularization of the affected ovary (20). Melcer *et al.* showed that ovarian torsion is associated with enlargement of the ovary on the basis of edema and free fluid (21). However, in the case of ovarian torsion, the gold standard is diagnosis laparoscopy. Practiced when the first signs appeared with the advantage of allowing detorsion and preservation of the adnexa and in order to preserve fertility in this age category, laparoscopy was used in our study only in 16.36% of operative cases, in correlation with surgeon experience regarding the use of this technique (22).

The torsion is a rare complication of malignant tumors, ranging in frequency from 1-6% in children and teens (23), the most common in germ cells tumors. In our study, the frequency of torsion in patients with malignant tumors is 7.99%, 6.66% of which are dysgerminomas. At the same time, dysgerminomas are the most common malignancies encountered in this age group, an aspect supported by the literature (24).

The use of a tumor marker both as a screening and as a diagnostic test for ovarian cancer is based on the identification in serum of an abnormal level of a specific marker, which reflects the systemic effect of the disease (25). There have been studied many tumoral markers: alpha-fetoprotein (AFP), carcinoembryonic antigen (CEA), carcinoid antigen 19.9 (CA 19.9), carcinoid antigen 125 (CA-125), β human chorionic gonadotropin (β-HCG) in order to detect and monitor malignant tumors, which are especially elevated in germ cell and epithelial tumors (26). Thus, they are essential tools in pediatric practice to exclude germinal tumors. In teenagers AFP and β-HCG are essential for assessing ovarian pathology. AFP is produced, in addition to germinal cells tumors by other tumors such as the pancreatic and liver neoplasia. However, the study led by Papic *et al.* demonstrated the specificity of AFP and β -HCG in ovarian malignancies (27). In the literature the sensitivity of this marker is 90%, with a specificity of 60%. In our study, we turned our attention to AFP, observing a preponderance of teens in the study group, thus obtaining a specificity of 70%. This marker is also used in staging and determining the doses and duration of administration of chemotherapeutics (28). In the case of tumors that do not produce AFP or β-HCG, studies have shown the possibility of using markers such as LDH, inhibin, TAG 72 glycoprotein or human epididymis 4 (HE 4) (29). In the management of malignant ovarian tumors in children, the desire essential is represented by conserving ovarian tissue without compromising cancer surgery principles being difficult to perform. In our study, the rate of ovariectomy is 30.95%, demonstrating the attempt to preserve ovarian tissue in all cases where this was possible. Interventions involving preservation of the adnexa were indicated in benign tumors, excision was recommended in case of malignancy.

In this study, the rate of interventions that preserved ovarian tissue was 68.99%, lower compared to the study led by I. Banli-Cesur, with a rate of 96.7% (30-33). The omission of a possible malignant tumor is the main concern of surgeons, the signs and symptoms being nonspecific. Tumor markers and imaging methods are a real support, but in the case of an emergency they cannot always be performed.

Benign tumors are most common in children and teens. Although there are no prospective and randomized studies on the management of ovarian tumors in this age group, the low incidence of malignant tumors and the preservation of fertility, advocate the approach of a surgical treatment after which the ovarian tissue is preserved. On the other hand, conservative non-surgical management can be prioritary, as highlighted in our study, considering the age, the possible implications on fertility and why not, the possible legal implications. Some of the ovarian initially evaluated neoplasia and which required symptomatic treatment may increase in volume later and may develop complications that this time will require surgery, as happened in 48 cases in our study. Surgery can be performed by laparoscopy, mini-laparotomy or laparotomy, ranging from aspiration of the cysts to salpingo-oophorectomy. Radical interventions such as adnexectomy in pediatric patients should be performed only if necessary, following the histological result. Laparoscopy is the method of choice for treating benign ovarian tumors without septa or vegetation, measuring less than 8 cm in maximum diameter (34). Preservation of fertility is essential, as surgery involving preservation of ovarian tissue is preferable whenever possible, as after an ovariectomy, castration may occur before the age of reproduction if torsion or neoplasm of the contralateral adnexa occurs (35). In the cases of torsion, the current approach is aimed at detorsioning and preserving the adnexa, despite its ischemic aspect. In this case, in one study conducted by Santos *et al.*, 97% of patients with a history of torsion in which detorsion and preservation of the adnexa were performed, did not show side effects, the ovary resuming its function later (36). Regarding the fixation of the ovary, the technique is controversial, some authors claiming that the fixation affects both the ovary and the connection between the follicles and the salpinx. This procedure is, on the other hand, recommended in cases where there is a recurrence, long ovarian ligament or single ovary (37). However, studies show an ovariectomy rate of 54-62.5% in case of torsion, in our study there is a decrease of this intervention, the rate being 49.33% (11, 38).

In our study we can also see an increased incidence of ovarian tumoral pathology in postmenarch patients, this can be explained by hormonal changes that occur at this age, a finding that is supported by other studies (36, 39). The pathology most frequently encountered in the literature is benign, as can be certified in the present study, the simple serous cyst being the histological type with the highest incidence of 58.99%. Functional ovarian cysts caused by anovulation or hormonal disorders are considered normal in adolescence, however in the case of persistent mass the possibility of a malignancy should not be ignored (27).

CONCLUSIONS

Ovarian tumors in children and teens are mostly benign, sometimes with nonspe-

cific symptoms, the most common being abdominal pain. In the management of these cases, the first step consists in the anamnesis and the clinical examination, later the ultrasonography representing an important investigation in the evaluation of the mass. Dosing of tumor markers is a second essential step in the evaluation, especially in the case of tumors that show signs of malignancy. Last but not least, the evaluation of suspicious tumors by computed tomography or magnetic resonance imaging is an important element that can dictate the conduct in such cases. Following these steps in the evaluation of ovarian tumors, allows their evaluation and a reduction in surgical interventions for benign tumors. Surgical management of ovarian masses should focus on ovarian preservation whenever possible. In the case of ovarian torsion, detorsion of the adnexa and preservation of the ovary is the recommended therapeutic approach.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

POST-MORTEM GENETIC INVESTIGATION OF CARDIAC DISEASE-ASSOCIATED GENES IN SUDDEN INFANT DEATH SYNDROME (SIDS) CASES

The sudden infant death syndrome (SIDS) is still one of the leading causes of post neonatal infants death. SIDS is defined as sudden death of an infant under 1 year of age, and the cause of death still remained unexplained after autopsy. In most cases, death occurs during sleep. A "triple risk model" for SIDS has been proposed and implies that the risk of SIDS increases if three factors concur: (1) a vulnerable infant, (2) a critical period in the development during the first months after birth, and (3) exogenous stress factors such as sleeping in prone position, smoking of the parents, and premature birth. Despite some successful campaigns to reduce these risk factors, SIDS is still the leading cause of death in post neonatal infants. Genetic variants affecting autonomic functions, neurotransmission, energy metabolism, and cardiac repolarization have been suggested to contribute to SIDS. These studies also showed that there exists a complex relationship between SIDS and inherited cardiac diseases. Long QT syndrome (LQTS), short QT syndrome (SQTS), Brugada syndrome (BrS), catecholaminergic polymorphic ventricular tachycardia (CPVT), and hypertrophic cardiomyopathy (HCM) have been described as a monogenic cause in a certain number of SIDS cases. The development of next-generation sequencing (NGS) offers new opportunities to investigate potential pathogenic sequence variations as an underlying cause of death in SIDS cohorts. Several studies suggest that in up to 30% of SIDS cohorts pathogenic mutations in cardiac channelopathy-associated genes contributed as a monogenic cause of death. In 3.5% of SIDS cases, a pathogenic variation in a cardiomyopathy-associated gene was detected. The detection of variants and its evaluation is important when counseling the family members in a SIDS case, but special precautions have to be made when a variant is considered to be pathogenic. In a recent study of variant analysis, 4.3% of pathogenic variations and 13% of "informative variations" have been found, which is a much lower percentage than that reported in the previous studies. In the present study, an analysis of genes associated with genetic heart diseases in a cohort of 31 SIDS cases was performed to investigate the presence of potentially causative variants, which may represent a predisposing risk factor for sudden death in infancy (Köffer J, Scheiper-Welling S, Verhoff MA, *et al*. Post-mortem genetic investigation of cardiac disease-associated genes in sudden infant death syndrome (SIDS) cases. *Int J Legal Med* 2021; 135: 207-212).

HOW NEGATIVE IS THE PRESSURE USED IN THE SURGICAL WOUND TREATMENT WITH NEGATIVE PRESSURE THERAPY (Abstract): The study aims to assess the significance of negative pressure therapy in the treatment of surgical wounds and using the ANSYS simulation software for fluid dynamics calculation will give us the possibility to determine the fluid flow dynamics inside the vacuum kit during its use. **Material and methods**: To predict the speed, pressure and temperature of the fluid inside a vacuum kit, we used numerical modeling, using the finite element method, of the gas fluid flow phenomenon. **Results:** The pressure of the liquid fluid is higher in the area of contact with the wound, compared to the pressure of the liquid fluid in the outlet area of the capillary tube, accentuating with increasing pressure applied to the end of the tube. 32% of the fluid pressure at the interface between the sponge and the wound. **Conclusions:** The rate of pressure transmission inside the sponge is variable favoring the appearance of ischemia areas on contact with the wound. **Keywords:** NEGATIVE PRESSURE, NPWT, WOUND TREATMENT.

Over time, the products used have become extremely complex and to find solutions to optimize them, such as solving problems of fluid dynamics, systems with moving parts (valves, pistons), where a transient analysis of phase systems is required due to heat exchange (cold / hot) and systems with complex physical phenomena, such as interference between liquids and surfaces requires the use of such computer programs because high quality products can no longer require engineers to rely on the study of phenomena the system is subject, addressing each one separately, but they must be thought of as a unitary whole taking into account in particular the dynamic interaction between them (eg the program is used in the conversion of nuclear waste into stable residues, having the ability to accurately predict mixtures required for stabilization).

The ANSYS simulation software for fluid dynamics calculation (CFD) will give us the possibility to determine the fluid flow dynamics inside the vacuum kit during its use. The capabilities of the software product in fluid flow analysis can be used to both design and optimize new devices

and to troubleshoot existing negative pressure systems, regardless of the phenomena studied.

A study, published by Maier *et al.*, Provides information showing that positive pressure also develops on the surface of the wound that meets the sponge of the kit, this being in contradiction with the theoretical considerations of device operation. In the study, pressure-measuring sensors placed on the wound were used, which recorded changes of up to + 26 mmHg in the contact areas between the sponge and the wound (1).

Starting from this study, we aim to analyze the conditions for the development of pressure both inside the sponge and at the contact surfaces between it and the wound, to evaluate the homogeneity and distribution of suction at different set suction values, the flow rate of secretions from the wound to the collecting container, using the polyurethane (PU) sponge.

MATERIAL AND METHODS

The analysis of the flow of liquid fluids through isolated systems demonstrates that the velocity, pressure and temperature of the fluid change continuously. To predict the speed, pressure and temperature of the fluid inside a vacuum kit, we used numerical modeling, using the finite element method, of the gas fluid flow phenomenon.

To solve the problem, we chose the ANSYS-FLUENT program which consists of the solver specialized in fluid flow phenomena.

The three-dimensional geometric model was made using the INVENTOR design program, developed by Autodesk USA. The geometric pattern was assimilated with a porous polyurethane medium, which has an open surface - in contact with the wound, and on the other surface is provided a port that comes into contact with a thin tube with variable geometry.

Discretization of the domain was performed using the unstructured tetrahedral networks from the existing software package in the Fluent solver, according to the rules of good practice in the field. The first figure presents the network of "finite elements", created for the considered model, which contains a number of 159,474 nodes, respectively a number of 205,093 tetrahedral elements.

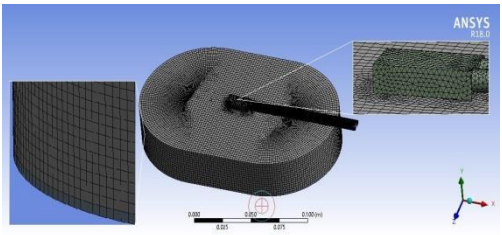

Fig. 1. The discretization networks applied to the model

The establishment of the limit conditions and the selection of the turbulence model was made according to the lines of good practice, valid in the field.

RESULTS

Figure 2a-d shows the variation of the fluid pressure at a negative pressure of 100 mmHg in the xOy –fig planes. 2a, and xOz - fig. 2b, as well as at two different points in the xOy plane figures 2c and d, under conditions imposed by the simulation. In figures 2e and 2f are represented the variation of the fluid pressure at a negative pressure of 150 mmHg in two different points in the xOy plane - figures 2e and 2f, under conditions imposed by the simulation.

Inside the model, the fluid has variable pressure, high values being registered towards the lower area of the polyurethane sponge, below the isosurface with the pressure of 13520 Pa (fig. 3).

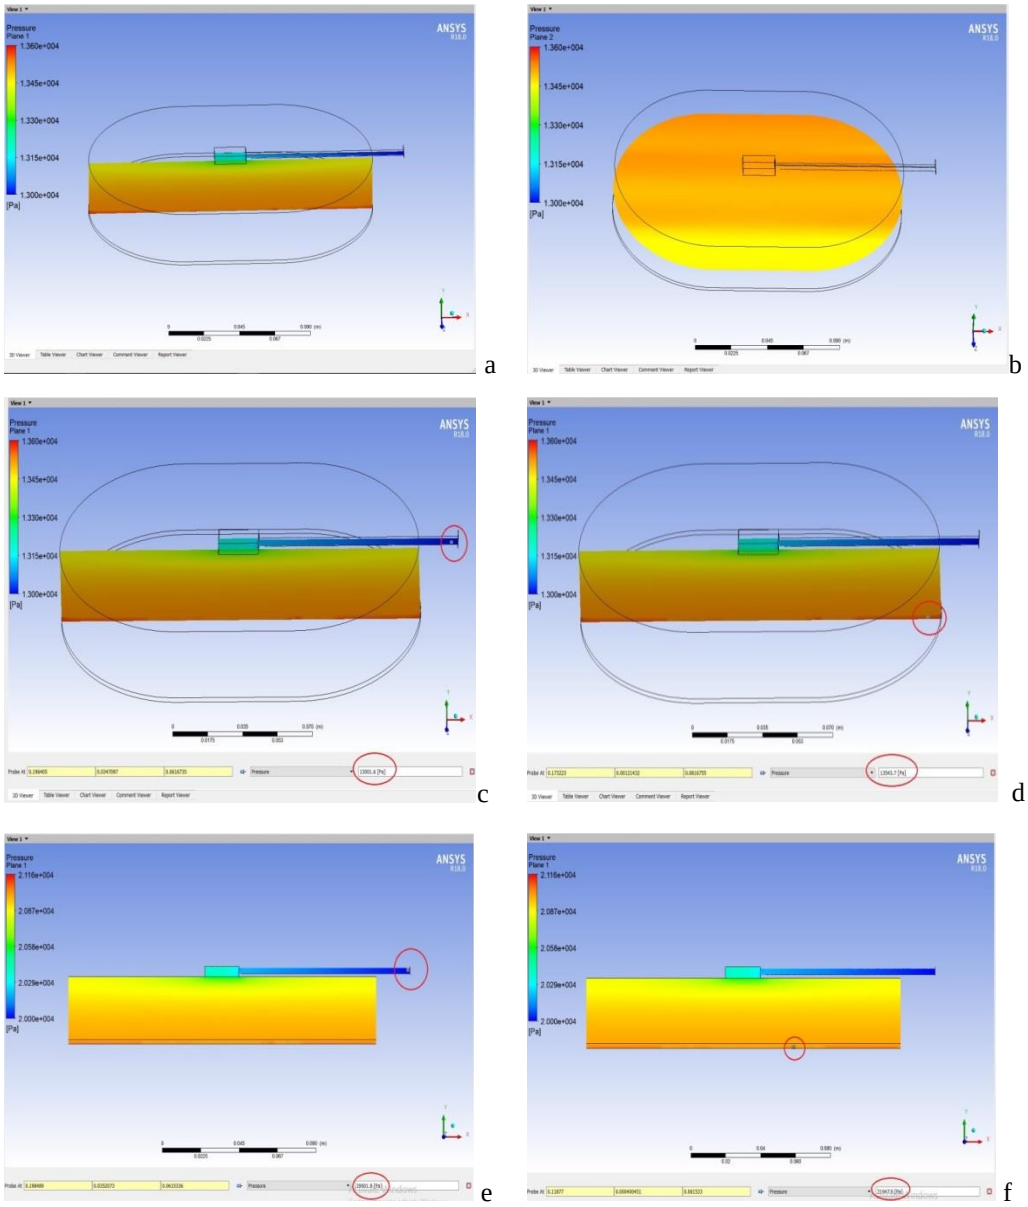

Fig. 2 a-f. Fluid pressure variation when setting the negative pressure system at 100 mmHg in: a xOy plane (bending = 13332 Pa); b) xOz plane (skew = 13332 Pa); c) at a point in the xOy plane located at the outlet of the suction tube (bending = 13332 Pa); d) at a point in the xOy plane located at the contact with the wound (skew = 13332 Pa); e) at a point in the xOy plane located at the outlet of the suction tube (bending = 19999 Pa); f) at a point in the xOy plane located at the contact with the wound (bending = 19999 Pa).

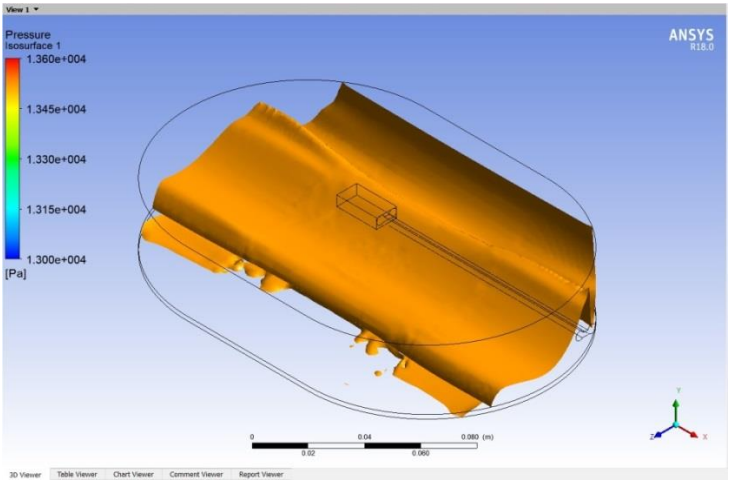

Fig. 3. Isosurface with average fluid pressure p = 13520Pa - system set at 13333Pa (100 mmHg).

DISCUSSION

The theoretical results obtained by finite element analysis show that, at the level of wounds, the suction pressure of the fluid is unevenly distributed, which determines, according to Willy *et al.*, the appearance of ischemic areas.

The size of the ischemic areas increases with increasing suction pressure. Fluid velocity is minimal at the sponge-wound interface, which causes slow fluid flow, which favors the appearance of edema and ischemic areas (2). The low flow rate of the fluid, both at the wound-sponge interface and inside it, determines the inability of the liquid flow to detach and mobilize the debris.

The theoretical results obtained, combined with existing clinical studies in the literature, converge to the fact that the application of negative pressure therapy in the treatment of wounds requires the use of an optimal fluid flow regime to prevent the formation of edema and ischemic areas of wounds.

Theoretical considerations and contributions made in the study refer mainly to the physical phenomena and interactions that take place inside a vacuum kit used in the negative pressure therapy of acute and chronic surgical wounds, because we consider that the postoperative results are closely related to the configuration his.

In the xOy plane, the pressure of the liquid fluid is higher in the area of contact with the wound, compared to the pressure of the liquid fluid in the outlet area of the capillary tube (fig. 2a). This increase, of approximately 4% (fig. 2c *vs.* fig. 2d), is accentuated with the increase of the pressure applied at the end of the tube and is due to the porous elastic environment and the complicated capillary system. Thus, the increase of the pressure applied at the end of the tube (from 13333 Pa = 100 mmHg) - to 19999 Pa = 150 mmHg) determines the increase by over 32% of the pressure of the liquid fluid at the interface between the sponge and the wound (fig. 2e and fig. 2f).

Our own studies, performed with the

help of finite elements, on the phenomenon of flow of liquid fluids through porous media, show that the rate of pressure transmission inside the sponge is variable (fig. 3), an aspect that contradicts the results obtained by Willy *et al.*, in the study on the suction effect of the polyurethane (PU) sponge. Measurements were performed on a sponge, at different distances (0-52 cm), in which he inserted 8 pressure sensors, arranged at distances equal to 7.5 cm, and applied different pressures, ranging from 50-200 mmHg , the measurements being performed at intervals of 25 mmHg. Each measurement involved stopping the experiment by setting the parameters to 0 and depressurizing the vacuum system, including the sponge, at which the information collection probes are located. The authors concluded that, when applying pressures of up to 150 mmHg, the transfer of pressures inside the sponge was performed at a rate of 1:1 over the entire length studied. Changes in the results obtained are highlighted at pressures above 150 mmHg, where, at a distance greater than 7 cm from the connector port, there are small deviations of the recorded pressure from the set one, but, as the study authors note, they are insignificant.

Wackenfors *et al.* and Saxena *et al.* showed, through animal experiments, the existence of areas of hypo- and hyperperfusion, in contact with the sponge with the wound. They observed hypoperfused areas and areas of ischemic tissue in the immediate vicinity of the wound, areas that had depths of about 2 cm in depth, which were directly related to the negative pressure set in the treatment of wounds. The increase in pressure causes the depth of the ischemic affected area to increase in depth (3, 4, 5). At that time, it was not possible to issue a uniform hypothesis from these studies, regarding the conditions of pressure and suction that lead to these changes, one of the reasons that prevent the issuance of such hypotheses being the limitations of the studies.

In the literature, there are postulated several theories on the action of vacuum on wounds in such systems applied in medical practice, based on observations made in the treatment of wounds, some of them being contradictory. The ischemia caused in these cases may be due to high negative pressures used in therapy.

Overall, there are uneven variations in the pressure of the liquid fluid inside the model, due to the complicated capillary system existing in the porous environment. The uneven differences in the velocity and pressure of the liquid fluid, the unevenness and anisotropy of the medium, as well as the deformability, elasticity, porosity of the sponge and the small wall thickness between two pores, make it work differently in the whole volume.

Based on the studies of Isago *et al.* and Maier *et al*, it can be suggested that the variation of the fluid pressure at the wound-sponge interface favors the appearance of ischemia areas, an aspect encountered in the group of patients introduced in the study (1, 6).

CONCLUSIONS

The elasto-plastic behavior of the porous sponge material during the operation of the kit allows the appearance of a pressure gradient inside the sponge accentuated appearance by increasing the pressure applied to the end of the tube. Thus, the increase of the pressure applied at the end of

the tube (from 13333 Pa = 100 mmHg to 19999 Pa = 150 mmHg) determines the increase by over 32% of the pressure of the liquid fluid at the interface between the sponge and the wound.

The existence of the pressure gradient inside the porous sponge determines the change of the sponge absorption rate and, implicitly, the favoring of the appearance of ischemia areas.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

EARLY CRITICAL RECURRENCE OF CARDIAC MYXOMA DEGENERATED INTO RHABDOMYOSARCOMA

Is presented the 50-year-old lady case, who underwent surgical resection of an intracardiac tumor occupying the left atrial cavity, which was histopathologicaly diagnosed as cardiac myxoma with moderate atypia. Monthly echocardiographic examinations demonstrated that there was no evidence of recurrent tumors during the first 5 months after operation, and the patient remained asymptomatic for further 3 months. However, she was sent to other emergency medical institution for the treatment of her sudden cardiogenic shock. It was informed that a redo operation for a recurrent intracardiac tumor was performed in an emergency basis and the second histopathological diagnosis was rhabdomyosarcoma. The present case implies that a follow-up schedule should be determined according to an individual basis, especially in a case suspicious of malignant pathology. In addition, other diagnostic methods independent of echocardiography would be expected for easier screening of possible recurrence (Hayashi Y, Yokoyama Y. Early critical recurrence of cardiac myxoma degenerated into rhabdomyosarcoma. *Chirurgia* 2021; 34(1): 55-57).

Med. Surg. J. – Rev. Med. Chir. Soc. Med. Nat., Iaşi 2021, 125(4): 550-562 doi: 10.22551/MSJ.2021.04.10

THE IMPACT OF COVID-19 LOCKDOWN ON THE LEVEL AND INTENSITY OF PHYSICAL ACTIVITY: A STATISTICAL ANALYSIS ON ROMANIAN YOUNG ADULTS

Cătălina Liliana Andrei[1], Andreea Catană[1], Andreea Mirică[2], Ionela Roxana Petcu[2], Andreea Letiția Arsene[1], D. F. Ciolan[1*]

THE IMPACT OF COVID-19 LOCKDOWN ON THE LEVEL AND INTENSITY OF PHYSICAL ACTIVITY: A STATISTICAL ANALYSIS ON ROMANIAN YOUNG ADULTS (Abstract): COVID-19 pandemic is affecting the lifestyle of billions of citizens and within this context, the measures of social distancing are prone to bring worrying shifts in physical activity habits. The present research aims to evaluate the changes in sport and physical activity among Romanian young adults. **Material and methods**: The sample includes 417 respondents (most of the interviewees being around 20 years of age) which filled the questionnaire between 5 to 11 March 2021 through an internet application. Our analysis evaluated the frequency and duration of physical activity and how it changed during the lockdown due to COVID-19 pandemic. **Results**: The results show that most of the respondents no longer perform any other physical activity except for walking, within the three studied time frames, with a slight increase during the state of emergency. There are no significant differences between sex and area of residency. The regression model revealed that a higher variation of the average frequency of physical activity after the state of emergency is explained by the model. **Conclusions**: Our study revealed that the average frequencies of physical activities before, during, and after the state of emergency are moderately correlated. **Keywords:** COVID-19, LOCKDOWN, PHYSICAL ACTIVITY, ROMANIA, YOUNG ADULTS.

Sudden introduction of physical distancing measures together with severe restrictions imposed to recreational areas lead to a radical lifestyle change of many individuals (1). The effects of such measures included increased anxiety, stress, and depression (2).

Exercising helps people maintain a positive emotional status as well as a bio clinical equilibrium of different comorbidities - diabetes, hypertension, cardiovascular diseases, and respiratory diseases (3, 4). Moreover, regular exercising increases emotional resilience to stress through the decrease of the heart rate and free cortisol (5). On the other hand, sedentary lifestyle and physical inactivity increases chronic disease risks and mortality risk associated with SARS-CoV 2 infection (6, 7).

The Centre for Disease Control points out various benefits of 30 minutes of moderately intense daily physical activity for all adults including a reduced risk of coronary heart disease, heart attack, diabetes mellitus,

colon cancer, hip fracture and high blood pressure (8, 9). Despite the benefits of physical activity, "only 1 in 5 adults and 1 in 5 high school students fully meet physical activity guidelines for aerobic and muscle strengthening activities" (10).

During the lockdown imposed due to Covid-19 rapid spread, the WHO recommended 150-300 minutes of moderate physical activity or 75 minutes of vigorous-intensity physical activity weekly (11). In a meta-analysis comprising 31 studies Bentlage *et al.* (2020) showed that physical inactivity due to lockdowns is a serious public health issue (12). Moreover, physical inactivity is a major factor in reducing life quality and life expectancy as it worsens pre-existing diseases of leads to new pathologies (13). Yan and Spaulding (2020) pointed out that regular exercising reduces the risk of severe acute respiratory distress, one of the main causes of death in SARS-COV 2 patients (14).

Countries all over the world implemented restrictions to address the COVID-19 pandemic. These restrictions resulted in a significant reduction in the intensity and amount of physical activity (15,16).

According to data from Eurostat (2014), in Romania, 71.8% of the adults from 18 to 29 years old registered 0 minutes of aerobic physical activity, the highest rate among the EU countries. Moreover, 67.1% of the adults aged 20 to 24 years old, 78.6% of the adults aged 25 to 29 years old and 81.5% of the adults aged 25 to 34 years old didn't perform any physical activity outside work. In 2018, according to the Special Eurobarometer on Sport and Physical Activity, 81% of the Romanian adults never or seldom exercise (17).

Schmidt *et al.* (2020) point out that sport activity of children and adolescents declined while recreational screen time increased, during the first (and strictest) measures of the COVID-19 lockdown in Germany. The study used self-reported data from children and adolescents between 4-17 years of age participating at two measurements points (before and during the first COVID-19 lockdown). The authors conclude that physical activity is highly context-driven (18). Research conducted by Wunsch *et al.* (2021) points out that there is a negative association between pre COVID-19 screen time and within COVID-19 physical activities. The authors advocate that a general reduction of screen time is recommended combined with an increase of the physical activity) in children and adolescents (19).

González-Valero *et al.* (2020) argue that physical activity is positively correlated to self-concept. Their research investigating physical, mental and emotional status in adolescents in relation with gender and type or amount of sport and physical activities points out a reduction in the overall self-concept for boys and girls during the COVID-19 pandemic. Additionally, academic self-concept for girls was higher during the lockdown (20). Bowden Davies *et al.* (2019), report that physical inactivity in healthy young adults is associated with cognitive decline and other deficiencies (21). Woods *et al.* (2020) state that circumstances pose significant challenges on the lifestyle during the COVID-19 pandemic (22). Encouraging people to engage in physical activities in a modern society generally affected by sedentarism, is urgent in the context of social distancing (23).

Given this special context, as well as the situation in Romania, the aim of this paper is to perform an analysis on the frequency and duration of physical activity

and how it changed during the lockdown due to COVID-19 pandemic in this country. More specifically, several research questions were formulated:

Q1: To what extent the frequency of physical activities after the state of emergency is correlated with the frequency of physical activities during and before the state of emergency?

Q2: What factors influence the frequency of physical activities after the state of emergency?

MATERIAL AND METHODS

Questionnaire design

In order to address the research questions, a questionnaire was distributed via social media between 5 March 2021 and 11 March 2021. It includes 16 questions grouped as following: 3 questions aimed at measuring the frequency of each selected physical activity before the state of emergency, during the state of emergency and after the state of emergency; 3 questions aimed at measuring the duration of physical activity before the state of emergency, during the state of emergency and after the state of emergency; 1 question aimed at measuring to what extent adults aged 18 to 35 enjoy physical activity; 1 question aimed at determining the most important factor that needs to be addressed in order to make physical activity part of the daily routine; 2 questions aimed at measuring the use of technology in tracking calories or physical activity; 5 demographic questions and one question aimed to determine whether the respondent worked from home or not. As this is not a standard questionnaire on physical activity level, one can find it in Annex 1.

Regarding the types of physical activities, we chose to collect data on walking, running, cycling, roller-skating and fitness/bodybuilding. The first four activities were chosen because scientific literature proposes various solutions cantered around them to increase physical activity levels for adults. For example, Collins and Fulton (2015) point out that walking is one of the simplest activities that can be easily added in adult's daily routine (24). Public bicycle sharing initiatives contributes to increase use of bicycles instead of cars and increases mobility in urban areas (25,26). Kardiyono *et al.* (2018) point out that roller-skating can be promoted as a recreational sport and socializing activity by the municipalities (27), as it has been acknowledged as an efficient cardiovascular activity (28). Fitness/bodybuilding was chosen because muscle training twice a week is essential for adults' mental and physical health (29), especially in women's case (30).

The extent adults enjoy physical activity might be an important motivational factor. Phoenix and Orr (2014) and Chelladurai (2011) argue that good mood during physical activities contribute significantly to initiating and maintaining a regular sports routine and might be the only motivator for some people to engage in physical activities (31, 32). Besides enjoying physical activity, scientific literature points out several other factors that might influence the extent adult exercise: appropriate health education (33), initiating national campaigns (34), study-work-free time balance (35). Therefore, our questionnaire accounted for these factors as possible predictors for incorporating physical activity into daily routine.

Regarding the use of technology, one should note that using technology to measure the level of physical activity and encourage people to do more exercise is an area which has been widely researched. For

example, Pal and Ho (2011) concluded that using pedometers along with establishing measurable objectives in terms of steps increases the level of physical activity (36). Moreover, several apps use gamification to encourage youths to exercise: BunnyBolt (37), Go Run Go (38), FitPaly Games (39), etc (37-39).

Sample size

According to the National Institute of Statistics there are 4821927 persons with age between 18-35 years in Romania in 2020. Based on this population, the sample size was computed for a 95% confidence level and a 5% confidence interval using the Sample size calculator proposed by Creative Research Systems (40), resulting in a required sample size of 384 persons. However, our sample size is higher, as 417 respondents completed the questionnaire.

Statistical methodology

In order to answer the first research question, questions 2, 3 and 4 of the survey were recoded as follows: points from 0 to 7 were assigned to each frequency (never=0, Less than once a week = 0.5, Once a week = 1, 2-3 times a week = 2.5, 4-6 times a week = 5, everyday = 7).

Next, three variables were computed as follows:

$$Average\ frequency\ of\ physical\ activities\ before\ the\ state\ of\ emergency = \frac{\sum_{i=1}^{11} Points_i}{11}$$

$Points_i = number\ of\ points\ per\ activity\ i$

i=1 for Walking outdoor, i=2 for Running outdoor, i=3 for Roller-skating outdoor,

i=4 for Cycling outdoor, i=5 for Other sports outdoor, i=6 for fitness or bodybuilding at a gym, i=7 for Cardio activities at a gym, i=8 for Other sports at a gym,

i=9 for Fitness/bodybuilding at home, i=10 for Cardio activities at home,

i=11 for Other sports at home

$$Average\ frequency\ of\ physical\ activities\ during\ the\ state\ of\ emergency = \frac{\sum_{i=1}^{8} Points_i}{8}$$

$$Average\ frequency\ of\ physical\ activities\ after\ the\ state\ of\ emergency = \frac{\sum_{i=1}^{8} Points_i}{8}$$

$Points_i = number\ of\ points\ per\ activity\ i$

i=1 for Walking outdoor, i=2 for Running outdoor, i=3 for Roller-skating outdoor,

i=4 for Cycling outdoor, i=5 for other sports outdoor, i=6 for Fitness/bodybuilding at home, i=7 for Cardio activities at home, i=8 for Other sports at home.

Next, the Pearson correlation coefficient and the significance test were computed between these three variables, for the overall database, by area of residency and by sex. The significance level was set to 1%.

In order to answer the second question several regression models were computed using questionnaire data with Average frequency of physical activities after the state of emergency as dependent variable. Independent variables were excluded if the coefficients were not significant.

RESULTS

Analyzing the responses of the questions at the end of the questionnaire, one can observe several characteristics of the respondents. Approximately 30% of the interviewees use an app for tracking calories while 44% use an app for tracking physical activity. Despite the benefits in terms of increasing the amount of physical activity of such apps, Lopez-Bueno *et al.* (2020) observed a slight reluctance in using such devices by the adult population (41). About 84% of the respondents worked or studied from home during the state of emergency and 60% of them still work or study from home full time at the moment of data collection. Additionally, 20% of the of the interviewees work or study from home part time at the moment of data collection.

With regard to the respondents' demographic characteristics, the answers show that approximately 32% of those participating in the study are males and 68% are females. 84% of the respondents live in urban areas and 16% live in rural areas. The distribution by age is skewed to the left, most of the interviewees being 20 years old. Regarding the employment status, 60% of the respondents are students, 26% of them are employees and 11% are both students and employees. According to the National Institute for Sports Research (2020) most of the Romanian adults that used to practice physical activity before the pandemic did not continue their routine during the pandemic (42).

Figure 1 displays the distribution of all the respondents by the frequency of performing specific physical activity before, during and after the state of emergency. As one can observe most of the respondents never perform any other physical activity except for walking. The situation is similar within the three studied time frames, with a slight increase during the state of emergency, when most of the respondents worked from home. Working/studying from home might be an important risk factor for inactivity and increased screen time (43). However, our results show that 54% of the respondents enjoy physical activities for recreational purposes. One possible explanation for this paradox might be the lack of time.

As one can observe from figure 2, 96% of all the respondents stated that maintaining work/study-free time balance is important or very important in order to integrate physical activity into the daily routine.

Before the pandemic, 92.7% of the permanent resident population aged 5 years old and over practiced walking at least 10 minutes/day for several purposes not only physical activity (44). According to the same source, 40.5% of the females aged 10 to 29 years old practiced regular walking, 5.8 pp higher than males. Our study showed that below 10% of the respondents practiced regular walking in 30 minutes daily sessions.

In 2019, 54.7% of the persons aged 18-35 years old practiced 180 minutes of regular walking (44). Our study showed that during the emergency state, 10% of the respondents walked 90 minutes per week, while after the emergency state, this value increased to 25%. Thus, one can observe that there a significant decrease in the share of persons that practiced walking after the emergency state as well as in the duration of such activities compared to the pre-pandemic year.

Considering cycling, roller-skating and other outdoor activities, data from the National Institute of Statistics (2021) showed

that 17.6 of the adults under 35 years old and teenagers practiced such activities on a weekly basis (44). Our study showed that 5.3% of the respondents went cycling, roller-skating or practiced other outdoor activities during the emergency state while 14% of them declared practicing after the state of emergency.

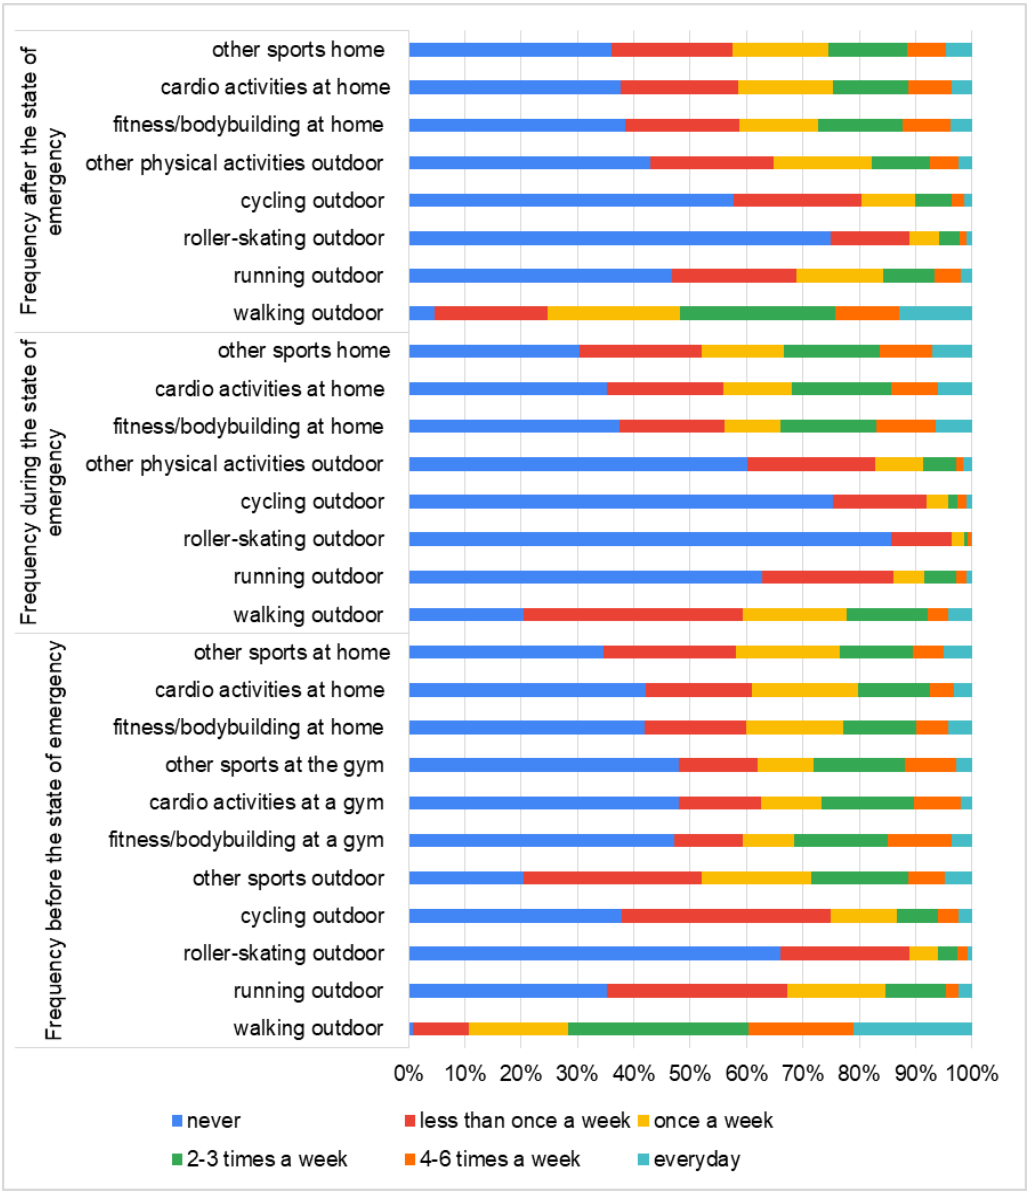

Fig. 1. The distribution of respondents by the frequency of performing specific physical activity before, during and after the state of emergency
(Source: designed by the authors based on questionnaire data)

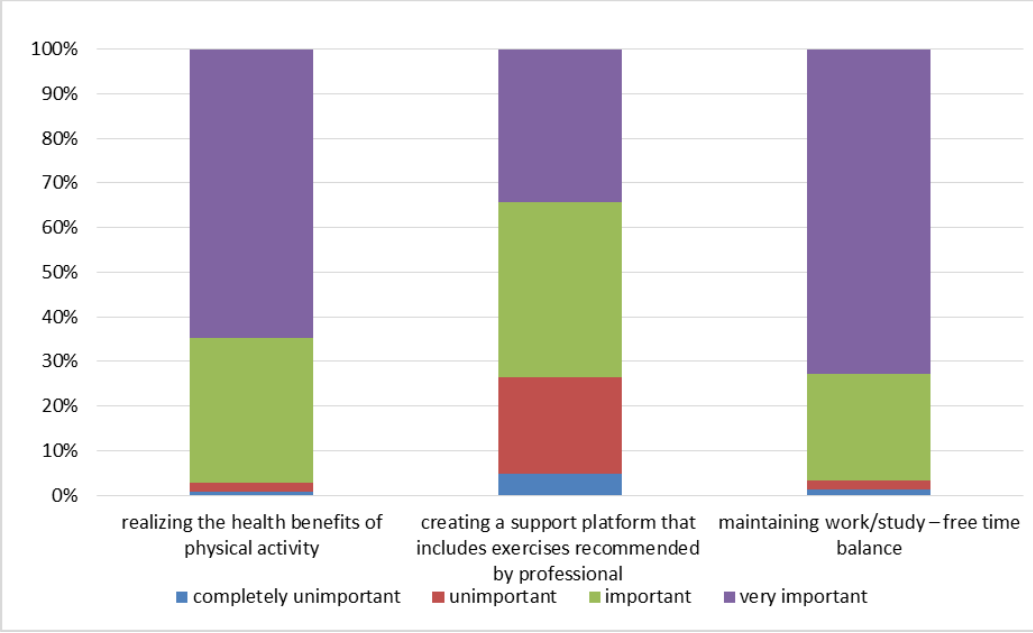

Fig. 2. The distribution of respondents by their attitude towards the factors that influence the process of integrating physical activity into the daily routine (Source: designed by the authors based on questionnaire data)

Also, realizing the health benefits of physical activity is important or very important for most of the respondents. As a consequence, authorities should actively promote the double advantage of staying active during lockdown, even if physical activities are mostly performed indoor: increased immune system and lower risk of non-communicable disease (34).

Table I presents the distribution of respondents by the duration of physical activities before, during and after the state of emergency. These activities include any kind of recreational physical activity. As one can observe, most respondents stated that the total amount of physical activity is at most 30 minutes daily. Our results are consistent with the results obtained by the National Institute for research in Sports (2020), that concluded most of the respondents exercised 60-90 minutes weekly (42).

Table II presents the correlation coefficients between the average frequencies of physical activities before, during and after the state of emergency. As one can observe there is a significant positive moderate correlation between the three variables. The results are similar when broken down by sex and area of residency.

The frequency of physical activity after the state of emergency is significantly influenced by the respondent's attitude towards such activities, the frequency of physical activity during the state of emergency and the frequency of physical activity before the state of emergency (tab. III). As the correlation coefficient between the last two variables is below 0.8, there is no risk for multicollinearity (45). More specif-

ically, 58% of the variation of the average frequency of physical activity after the state of emergency is explained by the model. All factors have a positive influence over the dependent variable, however the frequency of physical activity during the state of emergency has highest impact. The t-statistics is computed for each coefficient as the estimated coefficient divided by its standard deviation. The values for the t-statistics show that the coefficients for all variables are statistically significant.

TABLE I

The distribution of respondents by the duration of physical activities before, during and after the state of emergency

(Source: designed by the authors based on questionnaire data)

	Less than 10 minutes/day	10-30 minutes/day	30-60 minutes/day	More than 60 minutes/day
Before the state of emergency	14.39%	24.46%	36.45%	24.70%
During the state of emergency	28.78%	35.73%	26.62%	8.87%
After the state of emergency	18.23%	33.57%	32.61%	15.59%

TABLE II

The correlation coefficients between the average frequencies of physical activities before, during and after the state of emergency for the entire dataset, males, females, urban and rural residents respectively

(Source: designed by the authors based on questionnaire data)

	Average frequency of physical activities before the state of emergency	Average frequency of physical activities during the state of emergency	Average frequency of physical activities after the state of emergency
Average frequency of physical activities before the state of emergency	1	0.522** (total) 0.546** (females) 0.465** (males) 0.447**(rural) 0.534** (urban)	0.624** (total) 0.653 ** (females) 0.570 ** (males) 0.562** (rural) 0.647 (urban)
Average frequency of physical activities during the state of emergency	-	1	0.679** (total) 0.684** (females) 0.685** (males) 0.681**(rural) 0.694** (urban)
Average frequency of physical activities after the state of emergency	-	-	1

Coefficients and t-Statistics using the Average frequency of physical activities after the state of emergency as dependent variable

(Source: designed by the authors based on questionnaire data)

	Coefficient	t-statistics
Constant	-0.176	-1.481
Attitude towards physical activity	0.09*	2.557
Average frequency of physical activities before the state of emergency	0.374**	8.385
Average frequency of physical activities during the state of emergency	0.545**	12.448
*Significant at 10% level; ** Significant at 5% level		

DISCUSSION

Our analysis shows a significant change in physical activity among young adults in Romania. These findings are consistent with similar studies that examined related topics in surrounding countries. In general, the majority of the studies confirm that there is a concern on the changes in physical activity in healthy young adults as a result of social distancing imposed by the COVID-19 pandemic. Our findings are consistent with those of Barkley *et al.* (2020) who concluded that a well-established physical activity before the pandemic decreases the likelihood of a borderline sedentary life during the lockdown (46).

Recently, Sekulic *et al.* point out that the curve of physical activities among Croatian adolescents is driven by characteristics of the living communities, with a larger decrease in urban adolescents (47). Such aspect is in line with the research findings of Zenic *et al.* which point out that this decrease is mainly driven by the pandemic rules of social distancing as physical activity levels of Croatian teenagers rely on formal sport and organized recreational activities such as the ones in fitness centers or gyms (48).

In the light of such aspects, Guan *et al.* point out the importance of analyzing the situation of children from low income and middle-income countries during the COVID-19 pandemic, as per the known fact that a greater proportion of their population live in living-spaces that are exposed to overcrowding, making physical distancing challenging or virtually impossible (49).

One can observe a myriad of policies implemented by Governments to maintain some level of physical activity for the population. Governments have not always adopted measures in line with WHO recommendations for physical activity during this period. For example, in Belgium, people were actively encouraged to exercise at home and outdoor, in spite gym closures (50). Meanwhile, in Romania and Canada no such policies were issued (51).

Engaging in a daily exercise routine, socializing, offering support to people in difficult situations as well as using health apps are crucial in maintaining a good physical and mental health, therefore, physical activity at home is essential (52). A key element in ensuring an optimal level of physical activity is an efficient communication campaign through simple messages

(53). As our study showed that 90% of the respondents consider important or very important knowing the benefits of physical activities and 60% of them appreciate health digital platforms, promoting healthy physical activities should be focused on short and simple messages though dedicated pages.

Sport has proven to be an important element for development. The United Nations recognise the growing contribution of sport to the realization of the 2030 Sustainable Development Goals (SDGs) in resolution 70/1, entitled "Transforming our world: the 2030 Agenda for Sustainable Development". Physical activity and sport contribute to the general population well-being regardless of gender, age or ethnicity (54). The "Global action plan on physical activity 2018-2030" (55) pledge to introduced measures to promote and increase the global physical activity for a more active society. Regular physical activity should be integrated on a daily basis and can play a directly contribution to achieving many of the SDGs and promote United Nations values (55).

Considering that our study as most of the studies reported a decrease in physical activity and an increase in sedentarism, a public policy conducted by the World Health Organization and implemented in affected countries would be highly beneficial. Such policy should include online courses, walking, cycling and other outdoor activities. Moreover, considering the benefits of physical activity upon the positive evolution of patients infected with SARS-COV 2, targeted physical activity programs by comorbidities and supported by therapeutic options for the treatment of SARS-CoV2 infection (56) should be designed and implemented.

While this study examined a specific sample of the population, young adults (persons ages 18-35 years old), future research studies should be carried to evaluate the changes in sport and physical activities for other populations and groups of people. Literature suggests that social media can be further used to obtain statistical data (57, 58, 59). As countries develop economically, there is a rising concern of the sedentariness (55). With special attention focus on examining the changes in sport and physical activities beyond the COVID-19 pandemic and on sociodemographic factors driving these changes.

CONCLUSIONS

Our study analyzed to what extent the frequency of physical activities after the state of emergency is correlated with the frequency of physical activities during and before the state of emergency. Moreover, the factors that influence the frequency of physical activities after the state of emergency are identified. Our study revealed that the average frequencies of physical activities before, during and after the state of emergency are moderately correlated. Moreover, the average frequency of physical activities after the state of emergency is positively influenced by the attitude towards physical activity, the average frequency of physical activities before the state of emergency and the average frequency of physical activities during the state of emergency.

PREOPERATIVE PROGNOSIS OF COLON CANCER SURGERY: CAN THE RESECTABLE ARTERIAL LENGTH BE A VALID PREDICTOR OF LYMPH NODE COUNT? (Abstract) The number of harvested lymph nodes (LN) is an independent factor for colon cancer prognosis surgical quality. The vascular length from tumor margin to the central vascular ligature as measured pathologically is claimed to be prognostic factor and an indicator of surgical quality. We aimed to evaluate the anatomical variability of the colic artery from origin to the tumor margin (resectable arterial length - RAL) and to investigate its prognostic value by correlation with LN parameters. **Materials and methods**: We retrospectively included patients from the 2nd Clinic of Oncological Surgery, at the Regional Institute of Oncology, Iași, operated through complete mesocolic excision (CME), for colon cancer stages I-III, between 2017-2018, with available preoperative CT-scan. Ileocolic and inferior mesenteric artery RALs were measured on CT reconstructions. LN-parameters were extracted from electronic registries. Separately, on 50 normal CT-scans we measured RAL variation as generated by different tumor position on 6 standardized colon regions. **Results**: 36 colectomies were included, 25 right and 11 left hemicolectomies. Right colon RAL was mean (±SD) 98.9mm (±30.5) with a mean 39.7 (±12.1) LN count. Left colon RAL was 126.5mm (±29.0), with a mean 36.1 (±14.8) LN count. The *Pearson*-test showed no significant RAL-LN correlation (p=0.861). Large interindividual and intraindividual variation resulted from the 300 standardized RAL measurements, (mean±SD) 112.8mm ±42.1. **Conclusions**: Given the lack of correlation with a proven prognostic factor (LN), we cannot consider the RAL a reliable prognostic tool. Furthermore, its large anatomical variability makes it a difficult to use, unfeasible, surgical quality instrument. **Keywords:** COMPUTED TOMOGRAPHY COMPLETE MESOCOLON EXCISION, ARTERIAL LENGTH VARIABILITY, ILEOCOLIC ARTERY, INFERIOR MESENTERIC ARTERY, RESECTABLE ARTERIAL LENGTH, COLIC ARTERY TUMOR MARGIN LENGTH, SURGICAL QUALITY EVALUATION.

Complete mesocolic excision (CME) gradually becomes a new standard in the treatment of colon cancer and recently several indicators have been proposed to

evaluate the surgical quality (1, 2). Some studies propose the arterial length from the vascular tie to the tumor margin as a viable indicator for surgical quality of CME (2, 3, 4). Lymph node (LN) count and derived parameters are considered an independent prognostic factor in colon cancer (5, 6, 7, 8). Complete mesocolic excision (CME) with central vascular ligation (CVL) provides more LNs and a longer tumor to vascular tie length as measured on the pathological specimen, compared with conventional colectomies (2, 9, 10). However, CME is susceptible to surgical technique variability regarding the vascular ligature site that implies variable lymphadenectomy heights: D2 level (resection of the ileocolic artery up to the right side of the superior mesenteric vein or D3 level (at the origin of the ileocolic artery, on the lateral side of the superior mesenteric artery) as reported by various groups and national colorectal cancer societies (11, 12, 13).

Given that the mesocolic lymph nodes locate around the main vascular pedicle, some authors suggested that the pathological tumor to vascular tie length could also be a prognostic factor and derived from this that the length from vascular tie to tumor margin implemented its use in standardized pathological examination protocols evaluating the surgical quality of CME specimens (2, 14). However, this cannot accurately reflect the length of the arterial stump remaining in situ or its associated LNs, because the length of the main pedicle is variable and thus the arterial stump may be longer than the pathologist suggests (14, 15). Nevertheless, the vascular length could be a prognostic factor of the vascular length generated by patient anatomy and not by the quality of the surgical gesture.

We defined the resectable arterial length (RAL) as the distance from the D2 level of ligation to the nearest tumoral margin. We aimed to demonstrate the large intra-individual and inter-individual anatomical variability of the colic artery from origin to the tumor margin. Secondly, we investigated its prognostic value by correlation with LN parameters. Furthermore, we compare the CT measurement of RAL against the measurements on the photographed fresh specimen to validate the radiological measurement technique.

MATERIAL AND METHODS

We retrospectively investigated 2 groups of patients from the Regional Institute of Oncology (ROI), Iasi. For the 1st group we included patients from the 2nd Oncological Surgery Clinic, ROI, Iasi, operated by CME for stage I-III colon cancer, between 2017-2018, with a preoperative CT scan available. Images were extracted from the *"Patient Archiving and Communication System"* (PACS) of the hospital intranet. On the 2nd group we measured the inter-individual and intra-individual variability of the RAL on normal abdominal-pelvic CT scans.

CT measurement technique

Using Radiant DICOM Viewer (v.2020.2.3, Poznan, Poland) we identified and measured the length from the artery to the tumor margin as follows (fig. 1):

- the ileocolic artery (ICA) for those undergoing right hemicolectomy;
- the Inferior mesenteric artery (IMA) for those undergoing left hemicolectomy;
- full resectable arterial lengths (RAL) and theoretical D2 central vascular ligation corresponding lengths to tumor margin were measured.

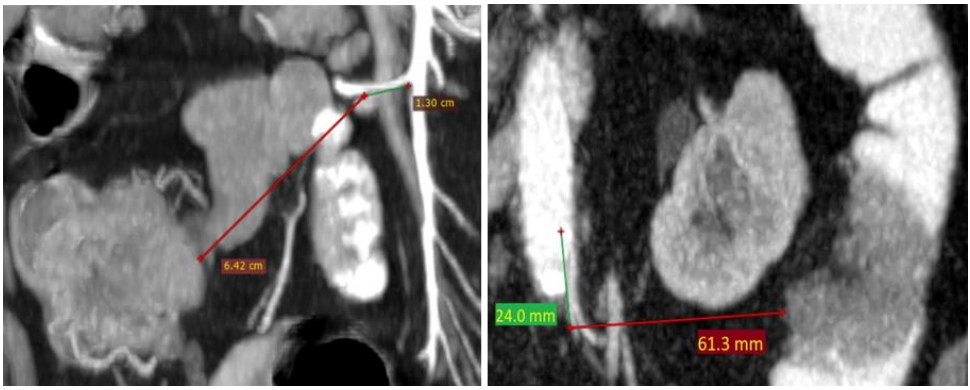

Fig. 1.A. Coronal CT view of resectable arterial length (RAL) measurement from the D2-theoretical central vascular ligation (D2-CVL) landmark to the tumor margin for colon cancer of the caecum. **B.** RAL from the D2 - CVL for descending colon.

We extracted pathological data regarding lymph node number and status from the integrated electronic system of our institution.

In order to validate the CT measurements, we performed a radio-pathological correlation of RAL on a subgroup of patients, by comparing the CT generated RAL with paired pathological measurements of resected arterial length up to the tumor margin, using fresh specimen photographies (figs. 2 and 3).

To investigate the anatomical variability of these arteries, we employed a retrospective study design on a 2nd group of patients which was investigated in order to account for the impact of the variation of the tumor's position on the colic frame upon the measurement of the resectable arterial length.

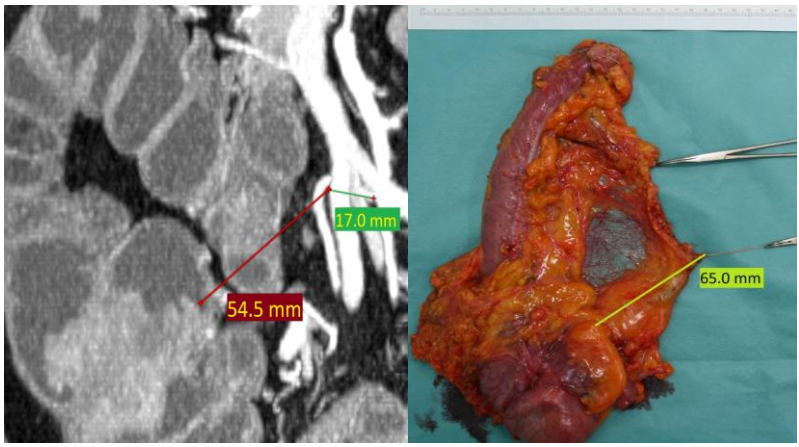

Fig. 3. The resectable arterial length correlation for colon cancer of the caecum; **A** - CT coronal reconstruction; **B** - fresh specimen

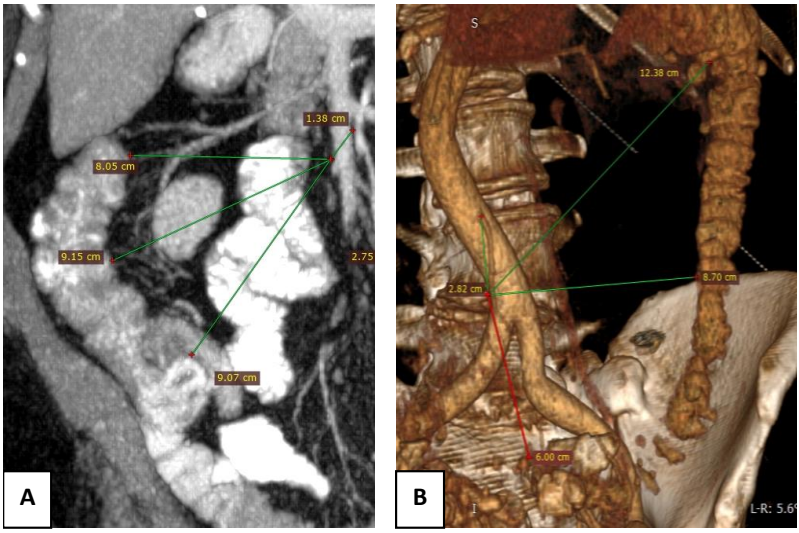

Fig. 4.A. Coronal CT reconstruction shows measurement of ileocolic resectable arterial length each standard point of a theoretical tumoral position on the right colic frame; **B.** 3D reconstruction CT shows measurement of the inferior mesenteric resectable arterial length to each standard point of a theoretical tumoral position on the left colic frame.

CT scan acquisition technique

The technical aspects of the imaging protocol for the patients scanned at the IRO was consistent with previous work published from our workgroup (16, 17). Patients had been scanned using a Bright Speed 16SL CT scanner with 16 detectors (GE Healthcare, Waukesha, WI, United States). The imaging station's protocol included a 16 mm, 1.25 mm increment, pitch value of 1.75, table speed of 35.0 mm per rotation, tube output of 120 kV and 260 mA. Arterial and venous phases were obtained using the automated bolus tracker

after injecting intravenously Iomeron 400® 816,5 mg/mL (Bracco Imaging, Milano, Italy) with an automated infusion pump at a rate of 2.50 mL/s. Data sets were reconstructed with a 1-3 mm section thickness and the reconstruction interval varied between 1 mm and 3 mm (idem). The CT scans had been originally ordered as for routine preoperative examination and not ordered for the purpose of this study.

Statistical analysis was conducted using the *IBM® SPSS® Statistics version 20.0* (IBM Corp) software. A p values lower than 0.05 was considered statistically significant.

RESULTS

The radio-pathological correlation of CT versus fresh specimen measurement of RAL was performed on 18 paired cases and the methods were similar with statistically significance: paired t-test showed a mean difference of 13.5 mm, p = 0.104.

After validating the CT measurement of RAL, we included 33 patients in our initial study group: 23 right colectomies and 10 left colectomies. The mean RAL (±SD) (range) for the ICA was 82.5 mm (±28.5) (20-127) and for the IMA 115.7 mm (±30.4) (70-170). The mean (± SD) LN number per entire specimen, was 39 (±12.6) for the right colectomies and 35 (±15.2) for the left colectomies. The *Pearson* correlation test between the RAL and LN count, did not reveal any statistical significance p = 0.822 for the whole group, neither when stratified for right (p = 0.372) and left colectomies (p = 0.183).

On the second study group we conducted 300 RAL measurements on 50 different patient computed topographies. Regardless of the hypothetical position of a tumor on the colic frame, the RAL vary significantly. Moreover, the RAL vary significantly within each of the 6 standardized points even if the level of arterial ligature is constant and the surgical gesture is standardized (figs. 5 and 6).

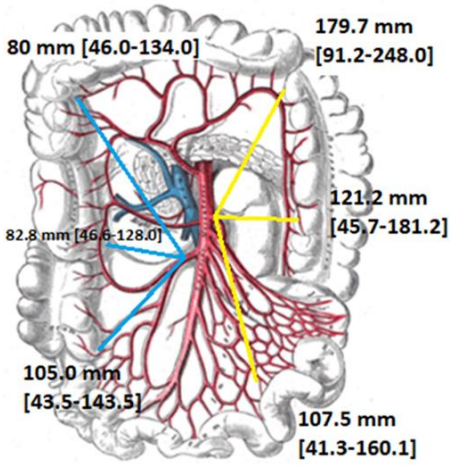

Fig. 5. Colon schematics with results of resectable arterial length to each of the 6 standardized points expressed as median mm (range).

The paired histograms below (fig. 7) show a statistically significant difference (p < 0.001) between the variances when *Levene's* test was performed between the ICA and IMA RAL compared to their respective D2-CVL lengths. This shows that although the length from the ICA origin to the right side of the superior mesenteric vein (*i.e.*, D2-CVL) is almost constant (15 mm ± 4 SD), whereas the D2CVL-right colon length varies greatly from 40 to 140 mm, mean 89.3, ±21.1 SD. Similarly, when comparing the left colon parameters, the length from the origin of the IMA to the emergence of the left colic artery (*i.e.*, D2-CVL) is almost constant (mean 40 mm ± 0.9 SD), whereas the D2CVL-left colon varies significantly (136 mm ±44.8 SD).

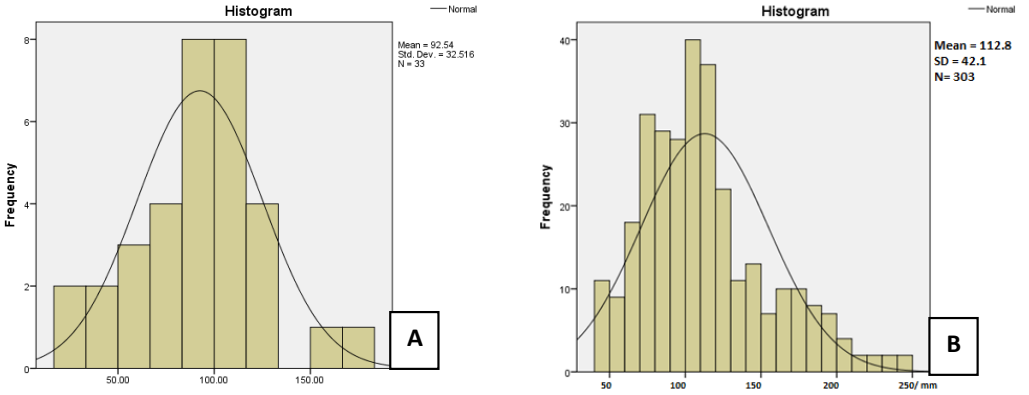

Fig. 6. A. Resectable arterial length from predicted D2-CVL to tumor margin – all 33 measurements showing very wide standard deviation ±32.5; **B.** Resectable arterial length from predicted D2-CVL to standard positions on colon – all 300 measurements showing very wide standard variation ±42.1.

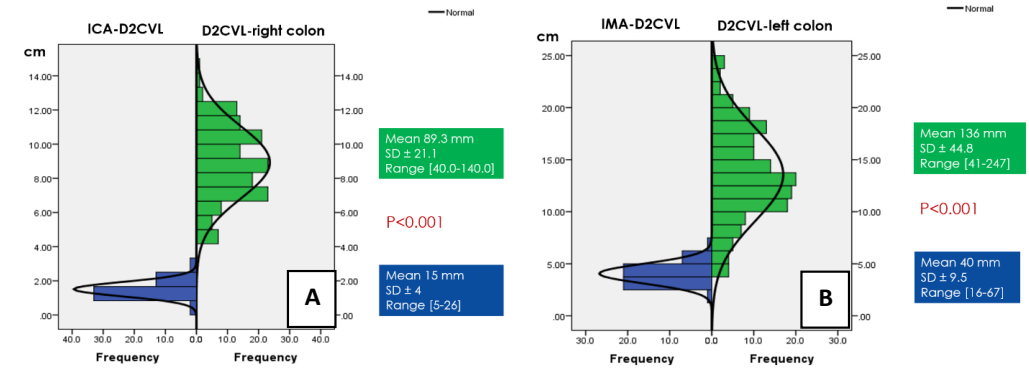

Fig. 7. Paired histograms showing the Levene's test for homogeneity of variances comparing the length from arterial origin to D2-CVL with the length from the D2 central vascular ligation to standard points on right colon (**A)** and left colon **(B)**.

DISCUSSION

In our study, the RAL varied significantly with regard to patient anatomy and tumor location and showed no correlation with the LN count. Nevertheless, it would be logical to consider that a longer colic arterial axis should be of important prognostic in some patients. A longer artery could represent a longer distance available for periarterial lymphatic drainage into the apical nodes. This could imply more ganglionic stations and would require more time for a sequential lymph node dissemination of cancer cells. However, this would be derived by local anatomy and not by surgical quality. This is also argued by several studies that have shown that that transverse colon cancer disseminates more frequently to the central LNs and extra mesocolic LNs and generally carries a worse prognosis (18).

As far as we know Solon *et al*. are the only ones to have had a similar study design. They reached the same conclusion as

us, stating that preoperative radiological calculation of pedicle length does not help predict the number of lymph nodes retrieved (14).

The mean RAL values for the ICA and the IMA in our study illustrated a high variation expressed as an increased standard deviation and a wide interval range both of which stand against a feasible indicator for surgical quality. The arterial length to tumor margin varies greatly dependent on patient anatomy (range 20-170 mm) and the pathologist cannot quantify the residual mesocolic/ arterial tissue remained in situ only by evaluating the pathology specimen.

Regarding limitations, a cohort of 50 patients is representative for the 2nd group, but larger cohort would strengthen the radio-pathological correlation of the 1st group. Only the ileocolic artery was chosen as representative for right colon cancer because of its anatomical constancy; the right colic artery has many anatomical variants and was excluded (19, 20).

Even after removing the effect of tumor location variation on the resulted length, the standard resectable arterial length to each of the 6 predetermined points on the colic frame is itself of significant variance, intrinsic to patient anatomy and hence it should not be used to discriminate between surgical specimens due to this intrinsic high variation.

Interestingly, the arterial length from origin to the vascular tie (i.e., arterial stump length) is significantly less variable compared with the entire RAL for all 6 hypothetical tumor positions on the colic frame (*Levene's* test, $p < 0.001$). Since the length of the arterial stump was proven to be the most constant vascular parameter after standardized surgery, our workgroup has recently published a validated postoperative quality assessment score that can select patients with high risk for locoregional recurrence in colon cancer based on the of colic the arterial stump length (17).

CONCLUSIONS

The resectable arterial length to tumor margin cannot be used as tool for surgical quality evaluation due to large variances.

Given the inconclusive correlation with a proven prognostic factor (LNs), we cannot consider the radiological resectable arterial length as a reliable prognostic tool.

CONFLICT OF INTEREST AND FUNDING

THE INFLUENCE OF THE OSSEOINTEGRATION METHODS ON THERAPEUTIC MANAGEMENT OF THE PATIENTS WITH TIBIAL PLATEAU FRACTURES - A RETROSPECTIVE STUDY (Abstract): **Aim:** The aim of study was to assess the influence of the osteosynthesis methods on the therapeutic management of the patients with tibial plateau fractures. **Material and methods:** The retrospective study was conducted on 63 patients (mean age 59.5 years; 37 males, 26 females) with tibial plateau fractures treated in Orthopedic Clinic - Traumatology Clinic Aschaffenburg-Alzenau (Germany) in the period 2015-2016. The mean values of pre-operatory interval, hospitalization time, surgical procedure duration, ablation time were calculated for each osteosynthesis method. Mann-Whitney tests were used for statistical comparisons between the implants systems in relation to the assessed parameters. Statistical significance was set up for $p<0.05$. **Results:** The pre-operative time was the highest for patients treated with rotating hinge (5.1 days), followed by plates + screws + Kirschner wires (4.0 days). The length of hospitalization was the highest for patients treated with rotating hinge (18.8 days), followed by plates (12.88 days). The duration of the surgical intervention was the highest for patients treated with plates + screws + Kirschner wires (95.0 minutes), followed by plates + screws (84.29 minutes). The ablation interval was the highest for patients treated with plates (12 days). Length of hospitalization was significantly higher ($p<0.05$) for patients treated with rotating hinge *vs.* alternative implants systems. **Conclusions:** It is very important to correlate the parameters related to the patients' management with implants and other relevant factors (systemic status, surgeon experience, soft tissues status, osteoporosis) to optimize the decision- making process and the long-term results of the treatment of the tibial plateau fractures. **Keywords:** TIBIAL PLATEAU FRACTURES, MANAGEMENT, IMPLANTS, OSTEOSYNTHESIS.

Tibial plateau fractures, accounting for 1-2% of the tibial fractures (1), and 1.7% of all human fractures (2), are found in a large range of lesions (OTA/AO classification). While teenagers and young adults has more frequently cominutive tibial plateau, unicondylar or bicondylar tibial plateau fractures are found most frequently in elderly people (2). The prognosis of these fractures is influenced mostly by the lesions' mechanism, soft tissues status, postoperatively complications, neurovascular

status of the involved area (3). Tibial plateau fractures are associated to a large range of lesions (OTA/AO classification), which require various surgical approaches (4). The main therapeutic goals in the treatment of tibial plateau fractures are the restoration of the articular stability, the axial and rotational alignment of the limb as well as the stability and early motion of the joint (5). The decision whether to operate or not on a specific fracture is based on the fracture morphology, the soft tissues, the patient's status, and the expected limb axis and articular surface restoration. Some of the conditions required for surgical management are as follows: intra-articular displacement over 2 mm; metaphyseal-diaphyseal translation over 1 cm; angular deformity of > 10° in the varus-valgus or sagittal plane; open fracture (6). Open Reduction and Internal Fixation (ORIF) concept is the gold-standard in complete/complex fractures (AO/OTA 41 C1, C2, C3/ Schatzker IV, V, VI) while a staged approach is recommended to prevent soft-tissues complications (6). Orthopedic surgeons have at their disposal a large range of implants and osteosynthesis methods. The selection of the proper surgical approach to optimize the therapeutic management of patients affected by tibial plateau fractures has raised interest along with the innovative improvement of the implants systems and osteosynthesis methods.

In this context, we aimed to assess the influence of the implants systems on the management of the patients with tibial plateau fractures.

MATERIAL AND METHODS

The retrospective study included patients with tibial plateau fractures who were treated at the Aschaffenburg-Alzenau Clinic, Germany, between 2015 to 2016. A total of 63 patients aged 20-99 years (mean age 59.5 years) who met the inclusion/exclusion criteria were assessed. Inclusion criteria: patients with surgically treated tibial plateau fractures (medial and / or lateral or posterior plates; Kirschner wires; screws; rotating hinge implant system). Exclusion criteria: age < 18 years; patients who attended the Emergency Unit of the Aschaffenburg-Alzenau Clinic, Germany but refused surgical treatment opting for functional treatment. We investigated the influence of the implants/osteosynthesis methods on the therapeutic management (pre-operatory interval, hospitalization time, duration of surgical intervention, ablation time) of the tibial plateau fractures. The definitions of the assessed parameters were as follows: pre-operatory time (days) - time between patient' admission and day of surgery; length of hospitalization time (days) - time between patient' admission and day when patient leaved the hospital; duration of surgical intervention (minutes)- time between the beginning and the end of the surgical intervention; ablation interval (days)- time between osteosynthesis and the moment when implant was taken out. Considering OTA/AO classification, the tibial plateau fractures had the following distribution: 7.9% fractures class A, 58.7% fractures class B (B1.1 22.2%, B3.1 15.9%, B1.2 11.1%), 33.3% fractures class C. The distribution of the implants systems and osteosynthesis methods used in the therapy of the tibial plateau fractures was as follows:

- Implants: plates (P) (57.13%), plates + additional screws (22.22%), plates + screws + Kirschner wires (4.76%), rotating hinge (15.9%);

• Osteosynthesis methods: multiplates (2.56%), external plate + medial plate (23.06%), external plate (30.76%), external plate + Kirschner wires (7.69%), medial plate (30.76%), posterior plate (5.12%).

Statistical analysis was performed using *Microsoft Office Excel 2013* and *SPSS 19.0* for calculation of mean values and standard deviation (SD). Mann-Whitney tests were used to compare the implant system regarding the mean values of the assessed therapeutic management parameters (statistical significance, $p<0.05$).

RESULTS

Tables I shows the mean values of the assessed parameters (preoperatory time; length of hospitalization; duration of surgical intervention; ablation interval) and the results of the statistical comparisons between the implants systems.

The Mann-Whitney tests applied to the parameters for all implants systems found a single significant statistical difference: length of hospitalization was significantly higher for patients treated by rotating hinge implants *versus* alternative implants systems. It was not found any significant statistical difference between osteosynthesis methods regarding pre-operative time, duration of surgical intervention, or ablation interval.

TABLE I

Mean values and statistical comparisons between implants systems

	YES		NO		p-Value§

§Mann-Whitney U test					

Table II shows the mean values for each parameter in relation to the implants category. The pre-operative time was higher for patients treated with rotating hinge (5.1

days), followed by plates + screws + Kirschner wires (4.0 days), plates + screws (3.64 days), and plates (3.38 days). The length of hospitalization was higher for patients treated with rotating hinge (18.8 days), followed by plates (12.88 days), plates + additional screws (11.43 days), and plates + additional screws + Kirschner wires (10.67 days). The duration of surgical intervention was higher for patients treated with plates + additional screws + Kirschner wires (95.0 minutes), followed by plates + additional screws (84.29 minutes), rotating hinge (76.3 minutes), and plates (75.5 minutes). The ablation interval was higher for patients treated with plates (12 days), followed by plates + additional screws (10.17 days), plates + additional screws + Kirschner wire (10 days), and plates + additional screws + Kirschner wires (7 days).

TABLE II

Mean values of the surgical management parameters related to implant category

Parameters	Implants category			
	Rotating hinge	Plates	Plates + additional screws	Plates + additional screws + Kirschner wires
Pre-operative time (days)	5.10	3.38	3.640	4.00
Length of hospitalization (days)	18.8	12.88	11.43	10.67
Duration of surgical intervention(minutes)	76.3	75.50	84.29	95.0
Ablation interval (months)	7.00	12.00	10.17	10.0

DISCUSSION

We aimed to gain an insight about how the implants category can change therapeutic management parameters (preoperatory time; duration of the surgical intervention; length of hospitalization; time from surgery to ablation of implant) of the patients with tibial plateau fractures. The most common categories of tibial plateau fractures in the group of patients investigated in our study were type B (58.7%); the most frequent type B fractures were B1.1 (22.2%), B3.1 (15.9%) and B1.2 (11.1%).

The proper selection of the implants and osteosynthesis method has a major importance in the treatment success of the tibial plateau fractures. In our study, the most frequent implants used in the treatment of the tibial plateau fractures were plates (57.13%), followed by plates + additional screws (22.22%), rotating hinge (15.9%), and plates + screws + Kirschner wires (4.76%). Different implants categories can reduce or lengthen the optimal values of these parameters as reported by literature data. For example, different preoperative time (time between injury and surgical intervention) of tibial plateau fractures are associated with different incidences of complications (skin ischemic necrosis, superficial infections, deep infections) while the optimal moment for surgical intervention for patients with closed complex tibial plateau fractures is between 5-8 days (7), and 6-8 days (8) post-injury. It was reported 92.5 ± 14.5 minutes (83-107 minutes) average duration of the surgical intervention when tibial plateau fractures were treated with proximal tibia locking compression plate (9). In our study, we noticed different mean values between the assessed parameters evaluated for various

categories of implants systems, but without significant statistical differences. The only exception was the length of hospitalization in patients treated with rotating hinge, significantly higher ($p<0.05$) when compared with the other alternative implants. The highest length of hospitalization was found in patients treated with rotating hinge (18.8 days), followed by plates (12.88 days). The highest pre-operative time was found in patients treated with rotating hinge (5.1 days), followed by plates + screws additional + Kirschner wires (4.0 days). The highest duration of the surgical intervention was found for patients treated with plates + additional screws + Kirschner wires (95.0 minutes), followed by plates + additional screws (84.29 minutes).

Considering the importance of the treatment of the complete/complex tibial plateau fractures for the post-operative life quality, the selection of the implants and osteosynthesis methods in ORIF concept depends on OTA/AO classification, location of fractures and various risk factors for the success of the surgical treatment. In posteromedial and posterolateral fractures anatomical reduction and stable fixation allow the prevention of the secondary malreductions. Many studies report the frequent use of the combination plates and screws due to their volume and easy-to-use features. Plates with 3.5 mm diameter and screws with diameter less than 3.5 mm can support bone fragments with reduced surfaces and allows the placement of screws closer to the joint surface. Sun *et al* (2017, 2018) support the use of multi-hole plates associated to parallel placement of screws near to joint surface to minimize the post-operative failure rate (10, 11). However, locking lateral proximal tibial plates (LISS), a proper posteromedial fragment fixation cannot be achieved by screw direction (12, 13). ORIF is recommended also in anterolateral or medial approach depending on the fracture type. In most cases, the use of medial plate for coronal fracture cannot provide fragment stability and the posterolateral and posteromedial fragments need to be buttress-plated and/or fixed from posterior to anterior. In posterolateral approach are preferred plates and screws that function as a non-slip tool allowing the resistance to shear forces; the screw must be placed near to the apex of fracture to ensure a fixed position of the plate (4). In bicondylar fractures are recommended the side plates and locking screws to withstand the axial, rotational and bending forces (4). Lateral platform fractures involving posterolateral column are approached by locking plate fixation (lateral + posterolateral) or locking plate fixation + 1/4 tubular plate edge fixation, Kirschner wire tension band fixation, and hollow nail fixation (for upper tibiofibular joint) (14). A research group reported high success rate for extended anterolateral approach with lateral tibial locking compression plate fixation for patients with Schatzker type II or extended anterolateral combined with a medial approach and lateral tibial locking compression plate + medial locking compression plate fixation for patients with Schatzker type V or VI (15). As proper fixation of the posterolateral and/or posteromedial fragments is difficult to achieve through conventional anterolateral and medial approaches, the three-column concept was introduced in the treatment strategy (16). A more recent therapeutic approach that decreases the rate of mechanical complications and loss of reduction is based on polyaxially variable-axis locking plate fixation devices (17, 18, 19).

CONCLUSIONS

It is very important to correlate the parameters related to the patients' management with implants and other relevant factors (systemic status, surgeon experience, soft tissues status, osteoporosis) to optimize the decision- making process and the long-term results of the treatment of the tibial plateau fractures. Integrated orthogeriatric treatment should be the standard approach to the multidimensional needs of senior patients with tibial plateau fracture. That is why it is necessary, for senior patients with tibial plateau fracture, who have associated osteoporosis, to use a rotating hinge prosthesis to be used as the first option of treatment, to regain and improve the quality of life.

CONFLICT OF INTEREST AND FUNDING

NEWS

EFFECTS OF PROBIOTIC NVP-1704 ON MENTAL HEALTH AND SLEEP IN HEALTHY ADULTS: AN 8-WEEK RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED TRIAL

A direct link was shown between the gut microbiota and mental health via the gut-brain-microbiota (GBM) axis. The perturbation of this axis is involved in altered stress response and behavior and is believed to cause various psychiatric disorders, such as anxiety, depression and insomnia. The probiotic NVP-1704 consists of *Lactobacillus reuteri* NK33 and *Bifidobacterium adolescentis* NK98. Several studies have shown that NVP-1704 has a favorable effect on anxiety and depression in mice, therefore the aim of the study was to verify the outcome of administrating it to healthy adults. The study took place at the Seoul National University Bundang Hospital. The study group consisted of healthy adults in the group age 19 to 65 who have shown psychological stress and subclinical symptoms of depression or anxiety. The experimental group received 500 mg capsules of NVP-1704, which contained 2.5×10^9 colony-forming units (CFU) of microorganisms – 2.0×10^9 CFU of *Lactobacillus reuteri* NK33 and 0.5×10^9 CFU of *Bifidobacterium adolescentis* NK98, while de control group was given a placebo capsule, made of maltodextrin, created to look identical to the NVP-1704 capsule. Several questionnaires were applied throughout the study, regarding symptoms of stress, depression, and anxiety, as well as sleep quality and symptoms of insomnia: Stress Response Inventory (SRI), BDI-II (Beck Depression Inventory), BAI (Beck's Anxiety Inventory), Pittsburgh Sleep Quality Index (PSQI) and Insomnia Severity Index (ISI). A total of four hospital visits were necessary: the first one two weeks prior to administrating the capsule, the second one when the patients were divided into two groups, the experimental group and the control group and were instructed to take two capsules once a day, daily, for eight weeks, the third one after 4 weeks and the last one after 8 weeks. Participants taking NVP-1704 have shown a significant decrease in the BDI-II score compared to those on placebo, at both the third and the fourth visit. There was also a decrease in the BAI score in the experimental group in comparison to the control group at the third visit. The SRI score dropped significantly at the third visit and further reduction was observed at the final visit. Overall, the experimental group was shown to have noteworthy improvements in overall depression and anxiety symptoms, at both the third and last visit (Lee HJ, Hong JK, Kim JK, *et al.* Effects of Probiotic NVP-1704 on Mental Health and Sleep in Healthy Adults: An 8-Week Randomized, Double-Blind, Placebo-Controlled Trial. *Nutrients* 2021; 13(8): 2660).

THE EFFECT OF BILE DECOMPRESSION ON PRO- AND ANTIOXIDANT MARKERS IN THE COMPLICATIONS OF GALLSTONES ASSOCIATED WITH CHOLESTATIC JAUNDICE

THE EFFECT OF BILE DECOMPRESSION ON PRO- AND ANTIOXIDANT MARKERS IN THE COMPLICATIONS OF GALLSTONES ASSOCIATED WITH CHOLESTATIC JAUNDICE (Abstract)**:** Argumentation of optimal terms for a staged surgical approach in the benign complications of gallstones associated with cholestatic jaundice by assessing the effect of biliary decompression on pro- and antioxidant markers. **Material and methods:** Prospective study, selected 105 patients with complicated gallstones and associated cholestatic jaundice, divided into three homogeneous subgroups, dependent on evolutionary complication. Control group - 35 patients with uncomplicated gallstones. All patients in the study group followed the staged treatment protocol in obstructive jaundice, with the primary prerogative - internal biliary decompression by endoscopic papillosphincterotomy. Pro- and antioxidant markers were assessed at hospitalization, on the 1st and 4th day after decompression. **Results:** Malonic dialdehyde at hospitalization marked in all subgroups with statistically significant results compared to the control group: I - 12.11±0.64 mol/l [$p<0.001$ ($t=10.7$)], II - 11.12±0.53mol/l [$p<0.001$ ($t=10.9$)]; III - 13.16±0.44 mol/l [$p<0.001$ ($t=16.5$)]. The activity of the antioxidant system evaluated by superoxide dismutase values [$p<0.001$($t=6.4$); ($t=4.1$); ($t=5.7$)] and catalase [$p<0.001$($t=6.7$); ($t=5.6$); ($t=7.6$)] shows a decrease in all subgroups compared to the control group. On the 1st day after drainage, malonic dialdehyde values did not show statistical significance compared to the before decompression state [I - $p>0.05$ ($t=0.11$); II - $p>0.05$ ($t=0.91$)]. An obvious reduction of its activity was found on the 4th after decompression day [I - $p<0.001$ ($t=5.15$; II - $p<0.01$ ($t=2.6$); III - $p<0.001$ ($t=3.99$)]. The return of the antioxidant system in all subgroups to values relatively similar to the control group: superoxide dismutase [I - $p<0.05$ ($t=2.21$); II - $p<0.05$ ($t=0.0008$); III - $p<0.05$ ($t=0.33$)] and catalase [I - $p<0.05$ ($t=2.39$); II - $p<0.05$ ($t=3.52$); III - $p<0.01$ ($t=2.87$)] was found more than 4 days after decompression. **Conclusions:** The study demonstrated the positive influence of biliary decompression in the complications of gallstones associated with cholestatic jaundice for the reduction of a massive lipid oxidation and the creation of conditions for increasing the antioxidant capacity with the restoration of the body's biological balance, which is more pronounced 4-5 days after decompression, serving as criterion for the possibility of definitive resolution of gallstones in these terms. **Keywords:** COMPLICATIONS OF GALLSTONES, CHOLESTATIC JAUNDICE, OXIDATIVE STRESS, ANTIOXIDANT SYSTEM.

From the range of surgical pathologies of the organs of the hepato-biliopancreatic region, the most difficult to approach are the diseases associated with mechanical jaundice syndrome, being accompanied by the partial or total stoppage of the bile passage. Biliary lithiasis is one of the pathologies located in this area, with an incidence of 10-15% in the adult population, which frequently evolves with complications associated with cholestatic jaundice (1). Despite the improvement of the population's access to medical assistance, the emergence of new non-invasive and informative methods in the diagnosis of gallstones, the rate of complications associated with cholestatic cholemia in pathology remains high-10-20% cases (1, 2). Studies show choledo-cholithiasis as the main cause of jaundice, but acute biliary pancreatitis, acute cholecystitis, cholangitis, are also mentioned (2, 3). It is known that, over time, obstructive cholestasis causes variable functional disorders in several systems and organs, with the most severe repercussions in the liver (3, 4, 5). Some authors, in studies aimed at suppressing the metabolic activity of the liver in mechanical jaundice, associate the severity of jaundice with blood bilirubin values, which of course is an important marker (2, 4, 5). However, taking into account a single indicator is not enough to evaluate the complex changes that occur when there is an interruption of the bile passage. Recently, papers have appeared that associate liver dysmetabolism in jaundice with the universal mechanism of cell injury - oxidative stress (OS) (6, 7, 8). The notion of oxidative stress, according to the opinion of several researchers, includes all the oxidative damage produced by oxygen free radicals. It is defined as the imbalance between the free radicals - the prooxidant and antioxidant systems, in the conditions where the oxidants are more and have a destructive potential on the human body (6). In other words, oxidative stress is triggered by the imbalance between the amount of reactive oxygen produced in the body and its ability to eliminate it. (8). The presence of marked lipid peroxidation, which occurs in endotoxemia associated with cholestasis, is known in the literature (9, 10). Previous studies on the issue report that the suppression of the metabolic activity of the liver present in jaundice contributes to the reduction of the barrier function of the gastrointestinal tract, the inhibition of the immune system and hemostasis mechanisms, appreciating the mechanical jaundice syndrome as a medical-surgical emergency, which requires solving the biliary obstruction as early as possible (6). However, the laborious surgical interventions performed at the peak of the “icterus” to restore the bile flow, demonstrated an evolution with a significant number of postoperative complications, and a mortality of 15-40% (2, 11, 12), thus opening a field larger for staged surgical treatment, which has as its main goal biliary decompression in the first stage and definitive resolution of gallstones in the second stage (5;11). Because it contributes to the reduction of complications through the use of miniinvasive methods, the treatment in stages is currently widely used, although the problem of assessing the times of surgical interventions in stages, continues to be a topic of dispute. Also, the accessible literature data do not contain information, which aims to use the deviations of oxidative stress in the assessment of the times of surgical intervention in stages. In this context, we set out to try to argue the optimal

terms for a staged surgical approach in the benign complications of gallstones associated with cholestatic jaundice by assessing the effect of biliary decompression on pro- and antioxidant markers.

MATERIAL AND METHODS

The clinical research was carried out within the Clinical Base II of the Department of Surgery no.1 of SUMF "Nicolae Testemițanu". In order to achieve the goal, 105 patients with complicated gallstones and associated cholestatic jaundice were investigated, followed the staged treatment protocol in obstructive jaundice, with the primary prerogative - internal biliary decompression through endoscopic papillosphincterotomy (PST) with or without removal of the stone. 35 patients with uncomplicated gallstones were included in the control group. Biliary decompression by PST with or without removal of the stone in the study subgroups was performed after confirming the etiological diagnosis and establishing the indications. In subgroups I and II, endoscopic PST was practiced within 24-96 days of hospitalization, in subgroup III, in the case of preserved bile flow - after 4-5 days of conservative treatment. Indication for internal drainage via PST in subgroups was persistent cholestatic jaundice. The age of the patients varied between 51-72 years. Female/male ratio - 3/1. The criteria for including patients in the basic group were: the presence of complications of gallstones associated with cholestatic jaundice, confirmed by positive clinical and paraclinical diagnostic parameters, which met:

- clinical criteria: history of gallstones or biliary colic at the onset, the presence of jaundice during hospitalization;
- biological syndrome: battery of characteristic tests: - elevated values of serum bilirubin on account of the direct fraction, elevated values of alkaline phosphatase, elevated values of leukocytes, serum fibrinogen, serum urea, serum amylase, marked ALAT values and imaging confirmation of gallstones and diameter of main bile duct > 0.8 cm.

Cases that met the stated criteria were included in the study. The research was started after obtaining approval from the Institutional Ethics Committee.

Depending on the evolutionary complications present: the patients from the base group were divided into 3 homogeneous subgroups: I - acute cholecystitis, cholangitis and cholestatic cholemia în gallstones (n=35); II - chronic gallstone disease and cholestatic cholemia (n=35) and III - acute biliary pancreatitis and cholestatic cholemia (n=35).

The comparative evaluation of SO in subgroups was carried out by assessing in the blood serum the correlation between the intensity of peroxidic oxidation of lipids (POL) and the antioxidant potential. The tests were taken during hospitalization, until the start of treatment, on the first day after biliary drainage, over 4 days after drainage. In the case of a preserved bile flow, in subgroup III, the primary testing was performed after 4 days of conservative treatment. The intensity of POL was determined by the values of the final product of lipoperoxidation - malonic dialdehyde (MDA), assessed according to the procedure modified by Gudumac V. *et al*. (2010) (13). The antioxidant potential was expressed by the values of superoxide dismutase (SOD) and catalase (CAT). SOD activity was estimated according to the procedures modified by Gudumac V., Tagadiuc O *et al*. (2010) (14). CAT activity

was determined according to the method modified by Baciu E. and Nastas I. (1996) (15). The data of each case were recorded in a standardized form and processed, using the MS Excel program. The obtained results were compared and the changes in dynamics were related to the values of the parameters of the control group. The statistical analysis was performed. The discrepancy with the margin of error < 5% was considered statistically significant ($p < 0.05$).

RESULTS

Survey data and results of laboratory parameters in the study subgroups and the control group at hospitalization are presented in table 1. Depending on age and concomitant pathologies, the control group and the study subgroups were selected homogeneously, with an insignificant difference in subgroup I (p c/1 >0.05 (t=1.10); p c/2 <0.05 (t=2.55); p c/3 <0.01 (t=2.84)). The homogeneity of the subgroups is also with insignificant deviations between subgroups I and II (p 1/2 >0.05 (t=1.64); p 1/3 <0.01 (t=3.31); p 2/3 <0.01 (t=4.55)). The data analysis shows that the association of an inflammatory, progressively painful component presents the patient earlier for hospitalization, reducing the duration of jaundice until hospitalization (p 1/2<0.001(t=3.5); p 1/3<0.001 (t=8.6); p 2/3<0.001(t=9.6)). Statistically significant difference in the levels of biochemical markers of cholestasis: alkaline phosphatase (p<0.001(t=10.6); (t=8.2); (t=7.27)), direct bilirubin (p<0.001 (t=12.3); (t=12.5); (t=14.9)) in all subgroups compared to the control group, reveals the severity of the liver disease, which is correlated with inflammation markers - elevated values of fibrinogen, blood leukocytosis, neutrophils - p<0.001 in subgroups I and III. The assessment at hospitalization of the DAM values as the final product of lipoperoxidation, confirms a marked lipoperoxidation in all subgroups, compared to the control group (p<0.001 (t=10.7); (t=10.9); (t=16.5)). The activity of the antioxidant system evaluated by superoxide dismutase and catalase values shows a decrease in both SOD values (p<0.001(t=6.4); (t=4.1); (t=5.7)) as well as CAT (p<0.001(t=6.7); (t=5.6); (t=7.6)) in all subgroups compared to the control group.

Caption *: p<0.05*; p<0.01**; p<0.001***; p>0.05****- compared to the values of the control group

According to the results of the study, depending on the time interval after drainage, biliary decompression differently influenced the activity of the pro- and antioxidant systems. On the first day after endoscopic PST, a decrease in the level of direct bilirubin was found in all subgroups (I - p<0.01 (t=5.4); II - p<0.01 (t=3.3); III - p<0.001 (t=7.6)), but the level of leukocytes and neutrophils in the blood increased (I - p<0.05 (t=3.2); II - p<0.01 (t=1.6); III - p<0.05 (t=5.2)), factor that influenced a massive continuation of lipid peroxidation in all subgroups. The evaluation of the influence of internal biliary decompression on the prooxidant system by assessing the MDA values showed, on the first day after decompression, the maintenance of high values compared to the before decompression parameters in all subgroups. Characteristic for subgroups I and II, the increased values of MDA did not show statistical significance compared to the before decompression state (I - p>0.05 (t=0.11); II - p>0.05 (t=0.91)), characteristic of subgroup III in which the patients were initially subjected to a complex drug treatment, which reduced the degree of endogenous intoxication and contributed to the decrease of before decompression MDA values (p< 0.001 (t=8.66)), elevated MDA values after drainage showed statistical significance (p<0.001 (t=6.4)). An obvious reduction in lipid oxidation activity was found on the 4th day after decompression, when MDA values decreased significantly (I - p<0.001 (t=5.15; II - p<0.01 (t=2, 6); III - p<0.001 (t=3.99)), but not up to control group values. The influence of time-dependent biliary decompression on MDA values is shown in first figure.

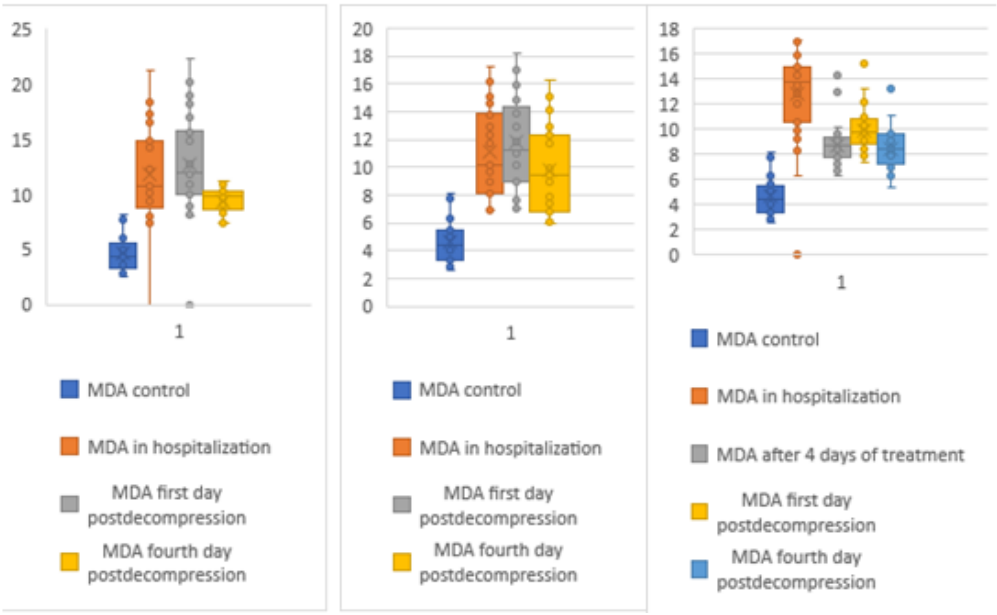

Fig. 1. Oscillation of DAM parameters in the complications of gallstones associated with cholestatic jaundice

The analysis of the influence of internal biliary drainage on the systemic antioxidant response in the case of endotoxemia with a marked lipoperoxidation in the complications of gallstones associated with cholestatic jaundice, also reported a variability in the values of SOD and CAT parameters depending on the elapsed time after decompression. Fluctuations in SOD and CAT values are shown in figures 2 and 3.

On the first day after PST, the values of SOD and CAT in groups I and II decreased insignificantly compared to before decompression values but showing a statistically significant decrease compared to the control group SOD (I - $p<0.001$ ($t=4.1$); II - $p<0.01$ ($t=4.8$)); CAT (I - $p<0.001$ ($t=4.1$); II - $p<0.01$ ($t=4.8$)), demonstrating the maintenance of an antioxidant response inability in this postoperative stage. In subgroup III, subjected preoperatively to standard complex therapy used in case of acute biliary pancreatitis, with potentiation of the antioxidant system through increased values of SOD (III - $p<0.001$ ($t=4.8$)) and CAT (III - $p<0.001$ ($t=7.4$)) before decompression, decreased values after drainage of SOD (III - $p<0.05$ ($t=3.04$)) and CAT (III - $p<0.05$ ($t=2.19$)), according to statistical significance, they showed a better antioxidant response capacity in these patients.

The increase in SOD and CAT values on day 4 after drainage exposes an increased potential of the antioxidant system at this postoperative stage (tab. II).

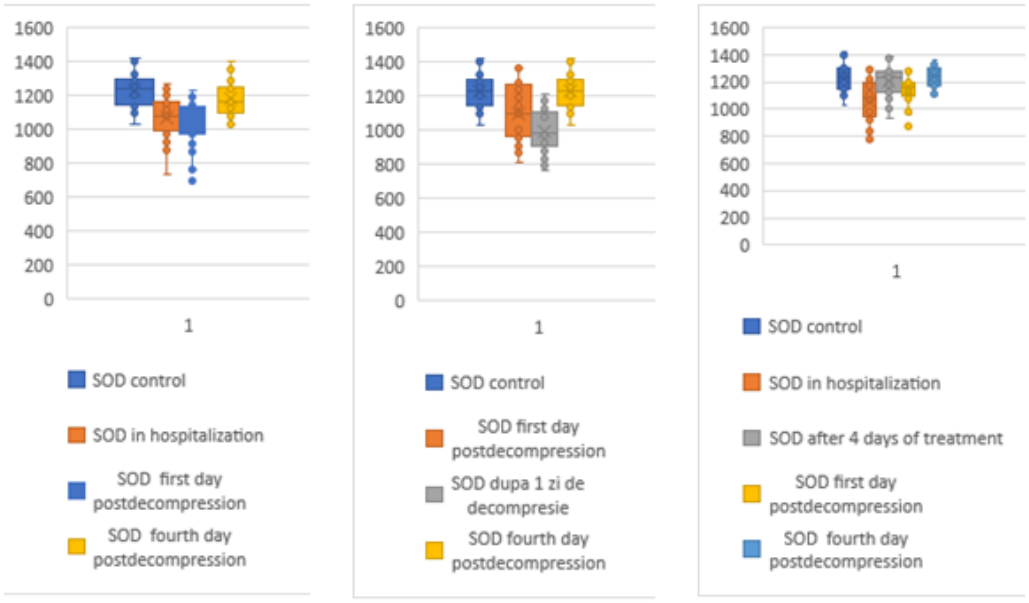

Fig. 2. Oscillation of SOD parameters in the complications of gallstones associated with cholestatic jaundice

TABLE II.

SOD and CAT parameters 4 days after decompression

DISCUSSION

According to the data accumulated in the literature, cholestatic jaundice, associated with various pathologies, is considered a complex surgical problem, presenting both diagnostic and therapeutic challenges (4, 5, 11). Early biliary decompression is recognized as the optimal method of treatment in avoiding functional and organic alteration of the liver. The ideal for the patient would be to resolve both the cholestatic jaundice and the etiological factor triggering cholestasis at the same time, an argument supported by some authors (17). However, practice has shown that these interventions are more often associated with complications and a slow postoperative evolution (16, 18). Staged treatment with the primary prerogative of biliary de-

compression is currently recognized and widely used in solving pathologies associated with cholestatic jaundice (4, 11, 19). However, the issue of operating times is presented controversially in the literature. Some authors, taking into account the high cost of diagnosis and treatment of these patients, claim that the definitive resolution of gallstones after decompression must be performed in the first 24-48 hours (18, 20). Others, focusing on the hepatic homeostatic disturbances, characteristic of lithiasis cholestasis, prefer for "late" cholecystectomy, in repeated hospitalization (4, 11,19), which according to studies can lead to a recurrence of complications (18, 20). The continuous study of the complex pathophysiological mechanism characteristic of the evolution of cholestatic jaundice requires solving the problem depending on the biological balance of the patient (11, 19).

It is known that the permeability of the biliary tree and the uncompromised drainage of bile into the intestine are important for a homeostatic balance of the body. Substances normally excreted in the bile, in the case of biliary obstructions, accumulate in the blood system and, together with the bile salts also accumulated, have systemic toxic effects, clinically manifested by prolonged infectious complications, coagulopathy, hypovolemia and endotoxemia, which can ultimately lead to to organ failure (2, 4, 21). Among the factors capable of modifying the normal functioning of biological membranes are reactive oxygen species, capable of inducing the phenomenon of lipoperoxidation, which contributes to the destruction of membrane lipid structures, consequently increasing the permeability of membranes with an unbalanced transport of ions (7, 9, 21). The attack of oxygen free radicals on cellular lipids results in the formation of aldehyde lipid hydroperoxide decomposition products, such as malonic dialdehyde, the increase in values denoting a pro-oxidant activity, which was also found to be significant in our study. MDA values 3 times higher compared to the control group were in all subgroups of the study before decompression. The pro-oxidant aggressiveness was also maintained on the first day after decompression with an involution 3-4 days after drainage, being correlated with the decrease in blood leukocytosis values ($p<0.01$ ($t=2.1$)). Analysis of the effect of internal biliary decompression on the prooxidant system demonstrated a decrease in lipid oxidation values after drainage, which is significant over time and is correlated with the decrease in bilirubin values and the inflammation syndrome.

The liver, as the body's metabolic center, has an important role in immunological processes and phagocytosis, thus being a source of antioxidants. It is known that serum bilirubin has the ability to inhibit lipid peroxidation, capturing singlet oxygen, thus being considered as a non-enzymatic liver antioxidant (7, 18, 22), a point that argues for an abundant production of all bilirubin fractions in all forms of jaundice. But the excessive increase in direct bilirubin values in an obstructive jaundice, turns it into a factor of aggression with the mobilization of other antioxidant defense mechanisms. According to studies, the decrease in SOD and CAT values correlates with the duration of jaundice and in prolonged cholestasis shows a late rebalancing (9, 18, 22). Our data reported in all study subgroups a no prolonged jaundice with a minimum duration of 1.48±0.06 and a maximum duration of 4.44±0.38 from onset to hospitalization, a moment that

correlates with direct bilirubin values, ranking all patients in the group with an average degree of severity (17, 21). The decrease in before decompression SOD ($p<0.001$ ($t=6.4$)) and CAT ($p<0.001$ ($t=6.7$)) is consistent with the severity of jaundice and the presence of inflammation. Comparative analysis of SOD results (I - $p<0.05$ ($t=2.21$), II - $p<0.05$ ($t=0.0008$), III - $p<0.05$ ($t=0.33$)) and CAT (I - $p<0.05$ ($t=2.39$), II - $p<0.05$ ($t=3.52$); III - $p<0.01$ ($t=2.87$)) with the values from the control group, time-dependent, reveals the return of the antioxidant system in all subgroups to values relatively similar to the control group 4 days after decompression.

Thus, our study demonstrates that in the case of the patient hospitalized early for complications of gallstones with a non-prolonged jaundice, classified in the medium severity group, the restoration of the capacities of the antioxidant system returns close to normal values 4-5 days after decompression, being a favorable predisposing factor in reducing intra- and postoperative complications, in case of a second stage surgical intervention in these terms. Therefore, the data-lot known in the literature about use of MDA, SOD and CAT values as diagnostic tests to evaluate the severity of jaundice (22, 23), we consider that these parameters and their correlations can be additionally recommended as indicator tests in determining the type of treatment, volume of surgical treatment and operative times.

CONCLUSIONS

Oxidative stress is an important pathogenetic element in the self-maintenance and exacerbation of the inflammatory response present in the complications of gallstones associated with cholestatic jaundice. Until the initiation of biliary decompression, in these patients, there is a significant intensification of the peroxidic oxidation of lipids, with a character of a chain oxidation process, and an increase in the level of the final product of lipid peroxidation-malonic dialdehyde, a fact that confirms the need for an immediate decompression. Antioxidant activity before decompression is also compromised, correlating with the degree of endotoxemia and severity of jaundice. It is obvious that, immediately after decompensation MDA maintains its values, yielding over time under a complex conservative treatment. Bile drainage, however, creates conditions for increasing the antioxidant capacity and restoring the body's biological balance, which is more pronounced 4-5 days after decompression, serving as a criterion for the possibility of definitive resolution of gallstones in these terms.

TREATMENT OF HEPATIC HYDATID CYST (Abstract): Hydatid cysts of the liver are benign lesions which require a wide range of surgical strategies for their treatment. The complex treatment of the hepatic echinococcosis has made great progress to less invasive therapy for this category of patients. The multimodal therapy is represented by administration of antiparasitic agents, interventional radiology, interventional endoscopy, eco- or CT-guided puncture, laparoscopy and associations between those. There are still difficulties in the treatment of complex echinococcosis, especially of the cases with one or more complications. **Material and methods:** We analyzed retrospectively a group of 74 patients who underwent surgery for complex hydatid cysts over several years at General Second Surgical Clinic, Iasi, Romania, between 2005-2021, in order to determine the evolution of the surgical treatment. We recorded the following parameters: age, gender, place of origin, serological and paraclinical investigations relevant to liver function and *Echinococcus granulosus* infection, affected hepatic segment, surgical technique, postoperative evolution and days of hospitalization, complications, recurrences and chemotherapy. **Results:** From the total number of patients admitted in our clinic diagnosed with hepatic hydatid cyst, only 30.7 % had surgical indication. We performed the surgical treatment of the hydatid cyst by laparoscopic approach in 35.1% of cases and a classic approach 56.8%. The surgical technique used in the most cases was partial peri cystectomy (n=54, 73%), total cysto-peri cystectomy in 8.1 % of cases (n=6), and simple drainage of the remaining cavity after the inactivation of the parasite, in the rest of the cases (n=14, 18.9%). The post-operative biliary fistula was encountered in 19 cases (28.4%), with no significant correlation between the surgical approach and the apparition of biliary fistula, the percentage being similar in laparotomy and laparoscopy, with only a 3% difference towards the laparotomy. **Conclusions:** The biliary fistula remains rather frequent complication of the hepatic hydatic cyst and it's a challenge to predict the apparition of this complication. **Keywords:** HYDATID CYST, LIVER SURGERY, BILIARY COMMUNICATION.

The human hydatidosis is a potentially serious, sometimes fatal condition caused by cysts containing the larval stages of the *Echinococcus granulosus* (*E. granulosus*) tapeworm that infect dogs and other canines. The tapeworm eggs are excreted in

feces of these infected animals and people become infected by ingesting them. The contamination can occur via hand-to-mouth transfer after handling dogs or objects contaminated with the eggs, or from consuming contaminated food or water (1).

Liver localization is the most common (over 60% of all localizations), infestation by digestive tract. The liver is the first filter in the path of the parasite, and the lung is the second filter and therefore the second location (about 30%). In Romania, the incidence of this pathology is increasing, with 5-6 cases per 100,000 inhabitants each year (2).

The uncomplicated hydatid cyst, in most of the cases, is asymptomatic. The diagnostic is established by random abdominal echography or during the surgery performed for another pathology. There are cases where the hydatid cyst was first diagnosed in surgical intervention performed for a different pathology, or even during necropsy. The hydatid cyst can be asymptomatic for many years, the clinical manifestations appear in case of large dimensions, depending on the location of the cyst and its complications.

At this time, the World Health Organization classification sets the staging of hepatic hydatid cysts based on the ultrasound aspect (tab. I) (3).

TABLE I.

Classification of hepatic hydatid cyst

Stage	Echographic aspect according to WHO Classification
CL	Anechogenic uniloculated cyst, with no echoes or internal sepsis
CE 1	Anechogenic cyst, with fine echoes inside, representing the hydatic sand – active cyst
CE 2	Cyst with multiple septa at the interior, giving it a multivesicular aspect or "honeycomb" aspect, with a uniloculated primary cyst – active cyst
CE 3	Uniloculated cyst with decollated proligere membrane ("waterlily sign") (CE3a) or daughter vesicles associating hypo-/ hyperechogenic images (CE3b) -cyst in transition phase
CE 4	Cyst with mixed content, hypo/hyperechogenic, without daughter vesicles – "wool clew" aspect-cyst in the degenerative phase
CE 5	Cyst with partial or totally calcified wall – inactive cyst

The multimodal therapy is represented by administration of antiparasitic agents, interventional radiology, interventional endoscopy, ultrasound or CT-guided puncture, laparoscopy and associations between those.

The classical surgery procedures used for the treatment of the hepatic hydatid cyst are divided, according to their attitude towards the pericyst, into procedures that do not involve pericyst resection (cystectomy) and procedures involving pericyst resection (partial peri cystectomy, pericystoresection, hepatectomy). They are associated with procedures that should treat the remaining cavity: external drainage with a drain tube, bipolar drainage of the cavity and the main bile duct, padding, omental plombage, drainage of the cavity by anastomosis with the stomach/ jejunum, pericysto-biliar drainage.

Laparoscopic interventions are primarily suited for cysts located superficially on the anterior surface of the liver. The types of interventions that may be performed by laparoscopy are peri cystotomy with cys-

tectomy, partial or total peri cystectomy, hepatic segmentectomy. The contraindications of laparoscopy are cyst rupture in the biliary tree, central cyst localization, cystic dimensions over 15 cm, thickened or calcified cystic walls (4).

MATERIAL AND METHODS

We analyzed the patient admitted between January 2005 and July 2021, in the General Second Surgery Clinic of Emergency Hospital Saint Spiridon Iasi with the diagnostic of hepatic hydatid cyst with indication of surgical intervention for the treatment of this pathology. The information was obtained retrospectively from the register of the hospital registry and the observation sheets, in full accordance with GDPR regulations governing the medical act (5, 6).

The aim of this study was to retrospectively determine the evolution of the surgical treatment. We recorded the following parameters: age, gender, place of origin, symptomatology, serological and paraclinical investigations relevant to liver function and E. Granulosus infection, affected hepatic segment, surgical technique, chemotherapy use, postoperative evolution and days of hospitalization, complications, recurrences. The affected hepatic segment was assessed by the Couinaud classification, currently the most widely used system to describe functional liver anatomy.

At admission liver function was investigated in all patients. Hepatic cytolysis syndrome investigated through serum transaminases (AST and ALT). Excretory biliary syndrome or cholestatic syndrome was evaluated by measuring the serum alkaline phosphatase and serum bilirubin values. Inflammatory syndrome was investigated by number of white blood cell and The level of C-reactive protein, and plasma fibrinogen values.

All patients received an abdominal ultrasound scan. Additional Computed Tomography was performed to patients that required additional imaging. Many patients also required other imaging investigations, such as a chest X-ray, needed for the anesthesiologist's evaluation.

After the radiologic evaluation the cystic stage was assessed according to the WHO classification and also the liver segments affected by the cyst.

RESULTS

The total number of patients registered between January 2005 and July 2021 in Between January 2005 and July 2021 in the General Second Surgery Clinic of Emergency Hospital Saint Spiridon Iasi, with the diagnostic of hepatic hydatid cyst was 274. From this number of patients only 74 (30.7%) had indication of surgical intervention. The rest of the patient had hepatic hydatid cysts less than 5 cm diameter, and the drug treatment was administered with the recommendation of periodic revaluation. In this category were included also patient with inactive cysts.

Of the total number of patients enrolled in the study, 50 were female and 38 were male. The average age of the patients was of 46 years, and more than half of the patients lived in rural areas.

The most commonly reported symptom was spontaneous or palpatory pain in the right hypochondrium. Other frequent manifestations were asthenia and jaundice/slight jaundice.

All patients received an abdominal ultrasound scan, cysts range from 7 to 18 cm in diameter, with an average size of the cyst was 10 cm, most of the cysts were CE3 and CE1 stages.

The cases were solved by ultrasound guided puncture (n=1; 3.3%), laparoscopic (n= 26; 35.1%) and classic approach (n=42; 56.8%) (fig. 1).

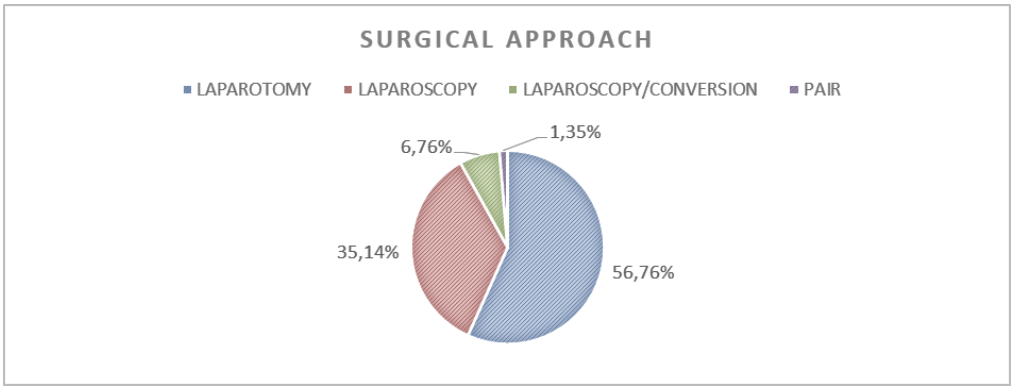

Fig. 1. Surgical approach of the hepatic hydatid cyst.

In the minim invasive approach, we performed inactivation-suction-drainage and partial perichistectomy. Using open approach, we did inactivation-suction-drainage, partial perichistectomy or total cystectomy. Laparoscopic treatment has significant correlation with type I-II (p=0.016) located in segments II, III and IV.

The surgical technique used in the most cases was partial peri cystectomy (n=54, 73%), total cysto-peri cystectomy in 8.1 % of cases (n=6), and simple drainage of the remaining cavity after the inactivation of the parasite, in the rest of the cases (n=14, 18.9%) (fig. 2).

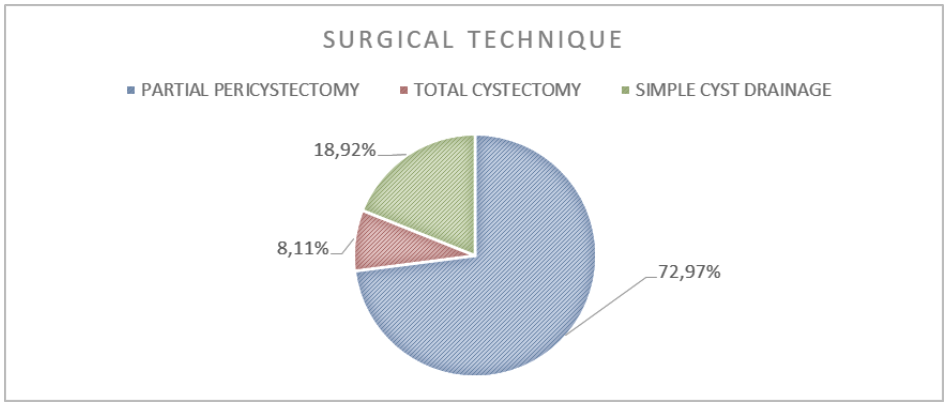

Fig. 2. The surgical technique

The post-operative biliary fistula was encountered in 19 cases (28.4%). In the graphic below we see than there is no significant correlation between the surgical approach and the apparition of biliary fistula, the percentage being similar in laparotomy and laparoscopy, with only a 3% difference towards the laparotomy (fig. 3).

There were no differences in age, sex, cyst type, alkaline phosphatase level, gamma-glutamyl transpeptidase level, alanine aminotransferase level, aspartate aminotransferase level, bilirubin level, and number of cysts and cyst locations between the patients with and without bile leakage. The treatment for the biliary fistula was conservatory, thus non-invasive procedure in 9.5% (n=7) and we did perform an Endoscopic Retrograde Cholangiopancreatography (ERCP) and sphincterotomy in 12.2% of the cases (n=9.5%) (fig. 4).

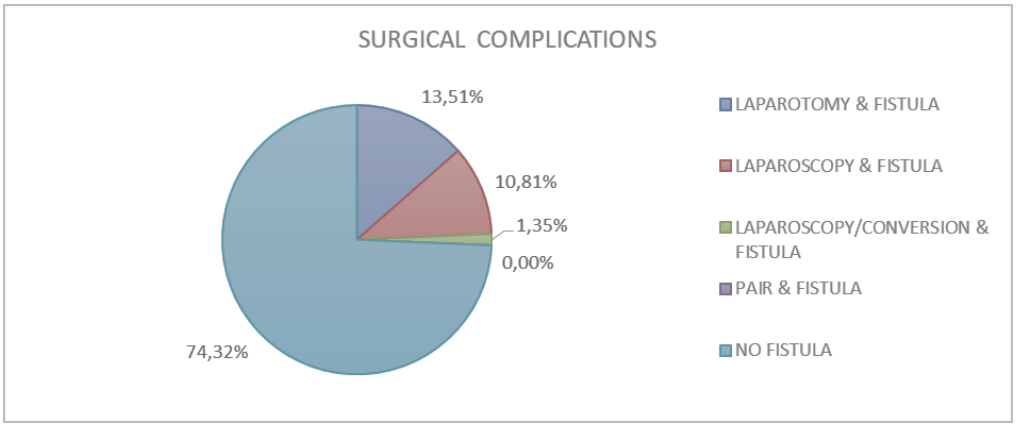

Fig. 3. Correlation between the surgical approach and the apparition of biliary fistula.

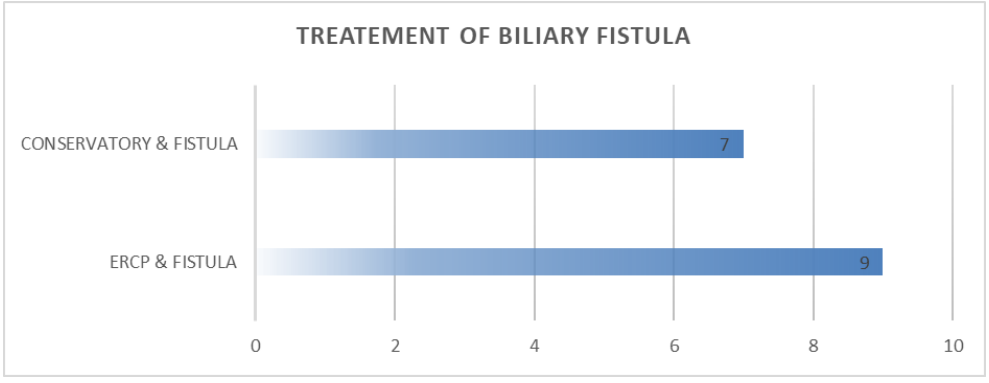

Fig. 4. The distribution of the biliary fistula treatment.

There was no significant difference in the postoperative evolution between laparoscopic procedures and open radical surgery (total perichistectomy).

We did not register significant correlations about recurrences and complications. Chemotherapy was used in 95% of cases, the election treatment was represented by Albendazol, administered in patient with weight of 60 kg or greater, the dose was 400 mg twice daily, for patients with a weight less than 60 kg we administered 15 mg / kg/ day given in divided doses twice daily with meals (maximum total daily dose 800 mg) for a 28-day cycle followed by a 14-day albendazole-free interval, for a total of 3

cycles. Monitoring of the blood counts and liver enzymes (transaminases) was done at the beginning of each 28-day cycle of therapy, with slightly increases values of liver enzymes in about 12 % of the patient, without significant secondary effects.

The most frequent hepatic segment localization of the hydatid cyst was in segment 4 (n=14, 18.9 %), in segment 7 of the liver in 8.1 % of cases for the single localization, and the multiple localizations most frequent hepatic segments were also 4 (22.9 %) and 7 (24.32%). The majority of the subjects have single-segment involvement 40.54 %.

In 6 cases the patient had other synchronous localization of the echinococcosis, with 2 cases of pulmonary hydatid cyst, one case of pulmonary and splenic localization, and one case of retroperitoneal localization, in the right subphrenic space and one case of localization in the abdominal wall in the preperitoneal space.

The post-treatment evolution was favorable in 72.6% of the cases, due to multiple therapeutic options and an ongoing development, with an average longer hospitalization period was obtained after open surgery treatment (18 days), a value of 15 days of hospitalization was obtained for minimally invasive techniques.

DISCUSSION

The liver is the most common location of the hydatid cyst, followed by the lung, with the approximate occurrence rates of 70% and 12%, respectively (7).

From 274 of patients with the diagnostic of hepatic hydatid cyst only a third had indication of surgical intervention. The rest of the patient, also included patient with inactive cysts, had drug treatment indication with the recommendation of periodic revaluation.

The drug of election was Albendazole, an anthelminthic medication with numerous indications such as cystic hydatid disease of the liver, lung, and peritoneum resulting from the larval form of the dog tapeworm, *Echinococcus granulosus* (8, 9). The most common adverse effects accompanying albendazole use are headaches and elevated liver enzymes because the drug is metabolized primarily by the liver, with 10% to 20% of patients experiencing elevated liver enzymes (12). Another adverse effect of this drug is induced myelosuppression, with pancytopenia and anemia (13). This is the reason we monitored of the blood counts and liver enzymes (transaminases) for each 28-day cycle of therapy.

Female patients were predominant in our group, with an age average age of 46 years, and more than half of the patients lived in rural areas. The usual hosts of E. granulosus is the domestic dog and livestock, have been hypothesized to be transmitted, at least partially, to humans through contaminated food. There is evidence that contaminated water is a potential disease determinant as well (12, 13). This transmission path explains the majority of patients infected from the rural area, because of the higher contact of this patients with the hosts of *E. granulosus*.

All patients received an abdominal ultrasound scan, cysts range from 7 to 18 cm in diameter, with an average size of the cyst was 10 cm. The smallest diameter is explained by the purpose of this study, with only surgical treated hydatid cysts because the indications for surgical therapy are cysts ≥7.5–10 cm (symptomatic or asymptomatic), cysts < 7.5–10 cm with complications such as compression to vasculo-biliary structures, fistulization to peritoneum, pleural cavity and adjacent organs (14).

The most commonly reported symptom

was spontaneous or palpatory pain in the right hypochondrium, a nonspecific symptom, the literature cites that this condition often remains asymptomatic for years before the cyst grows large enough to cause symptoms in affected organs.

Imaging, especially the ultrasound examination, was the basis for pre-surgical characterization of cysts. Most of the cysts were CE3 and CE1 stages and, in terms of size, between 7 and 10 cm diameter. Ultrasound examination is the easy, cheap and non-irradiation method the diagnosis of hepatic hydatid cyst (4).

The comparison between classic and minimally invasive surgical treatment revealed fewer complications and fewer necessary days of hospitalization in favor of the latter. There is no significant correlation between the surgical approach and the apparition of biliary fistula, the percentage being similar in laparotomy and laparoscopy, and no significant correlation between the other data registered and the bile leakage. Studies in the literature suggest that cyst diameter is an independent factor that is associated with a high risk of biliary-cyst communication in clinically asymptomatic patients (15-17). Our data didn't show a significant correlation between the diameter of the cyst and the apparition of the biliary fistula.

The treatment of election for the biliary fistula was Endoscopic Retrograde Cholangiopancreatography (ERCP) and sphincterotomy.

CONCLUSIONS

Hydatid disease has the benefits of a multimodal therapy. Chemotherapy, PAIR, laparoscopic surgery and open approach are completing themselves and not excluding each other. The biliary fistula remains relative frequent complication of the hepatic hydatic cyst and it's a challenge to predict the apparition of this complication. Endoscopic therapy is an effective mode of treatment for biliary fistulas complicating hepatic hydatid cyst.

NEWS

IT'S ALL IN THE RETINE LAYER: ASSOCIATION BETWEEN RETINAL NERV FIBER LAYER AND RISK OF COGNITIVE DECLINE IN PACIENTS WITH MULTIPLE SCLEROSIS

The multiple sclerosis and neurodegenerative process is present, and this is why there is a great desire to discover the perfect screening for multiple sclerosis consequence, for example cognitive decline. The researchers used the retinal study to explore the central nervous system. In this study, 64 patients underwent cognitive testing and optical coherence tomography imaging. The results showed that 36.0% participants were cognitively impaired. RLT of the macular retinal nerve fiber layer was associated with performance in TMT-B ($\beta = -0.259$). This study is a very exciting one, because it opens new directions for research in potential marker advocating further extensive neuropsychological examination (Sharon Jean Baetge, MSc, Michael Dietrich, PhD, Melanie Filser, *et al.* Association of Retinal Layer Thickness With Cognition in Patients With Multiple Sclerosis. *Neurol Neuroimmunol Neuroinflamm* 2021; 8: e1018).

A CHRONIC SCOPOLAMINE-INDUCED ANIMAL MODEL FOR COGNITIVE ALTERATIONS RESEARCH – ANATOMY AND METABOLISM

A CHRONIC SCOPOLAMINE-INDUCED ANIMAL MODEL FOR COGNITIVE ALTERATIONS RESEARCH - ANATOMY AND METABOLISM (Abstract): As long as complete etiology and curative treatment of Alzheimer's disease (*AD*) are not available, numerous animal species have been tested, but the ideal *AD* model has not been yet found. Although wild-type rodents do not develop β amyloidplaques or neurofibrillary tangles, rat species present some advantages for anatomical and functional *AD* modeling. **Material and methods:** Memory impairment was induced by intraperitoneal injection of 2 mg/kg *scopolamine (Sco)* into Wistar male rats. A control group received a similar injection with 0.2 mL physiological saline. Hybrid imaging acquisitions *^{18}F-fluorodeoxyglucose PET/MRI (^{18}F-FDG PET/MRI)* were achieved after 14 days of administration and euthanasia for harvesting rat brains and cerebral samples preservation was accomplished after 28 consecutive days of treatment. Specific cerebral regions were visually evaluated and quantified using *standardized uptake values*, then were correlated with the anatomic regions harvested, comprising: the cerebral cortex, hippocampus, thalamus, and cerebellum, a separate sample being collected for each side. **Results:** In coronal view, 56 cerebral samples, 160 cerebral *MRI*, and over 800 *^{18}F-FDG PET* cerebral images were obtained. Although anatomical macroscopic differences were not found between rats cerebral brains, *in vivo* functional imaging provided an obvious distinction between the saline-treated and the *Sco*-induced animals, changes that persist in long-term administration. **Conclusions:** The present study proves that the cerebral metabolism increase is maintained during chronic administration of *Sco*, with intense metabolism in the amygdala, the entorhinal cortex, and other specific cerebral regions specialized in memory processing. We emphasize the functional impact of *Sco*-induction correlated with anatomical implications after tissue dissection. **Keywords:** SCOPOLAMINE-INDUCED AD ANIMAL MODEL, CHRONIC INDUCTION, METABOLIC QUANTIFICATION, RAT BRAIN HARVESTING.

Alzheimer's disease (AD), the most common form of dementia, causes gradual to irreversible cognitive loss, as the brain loads with prominent deposits of specific proteins. As long as the complete etiology and curative treatment of *AD* are unknown, many studies examine brain changes in rodent models of *AD* (1, 2, 3, 4, 5).

AD phenotypes involve cognitive decline, imaging changes, and biomarker accumulations (6). *Neurofibrillary tangles (NFT), β amyloid (βA)* plaques, and neuritic plaques precede symptomatology by more than a decade (7). In *AD,* the glycolysis with oxidative deterioration of specific enzymes, the tricarboxylic acid cycle, and the biosynthesis of *adenosine triphosphate (ATP)* cause cerebral sclerosis, particularly in the hippocampus and cingulate cortex (8, 9). Glucose metabolism is decreased, partly due to oxidative damage. In some preclinical models (2, 3, 8), antioxidant molecules exert protective properties for the brain.

Thus, biochemical and imaging markers of neurodegenerative disorders must be investigated on animal models (10), but the ideal *AD* model has yet to be discovered. All models have been tested, from the ease of breeding and genetic manipulation of fruit flies to the longevity and the ability to exhibit amyloidosis (but not tauopathy) of dolphins and non-human primates (1).

Although wild-type rodents usually do not develop *βA* plaques or *NFT*s, probably due to their relatively short lifespan for pre-symptomatic phase development and molecular differences to human genes, the rat species have some advantages for *AD* modeling: ease of human handling, little susceptibility for external influence in spatial learning strategies and a large brain size that allows brain surgery (11). Despite all shortcomings, the increased availability of gene-editing tools could develop a multitude of new rat genetic models, from the suitable but less complete model, obtained in a shorter time frame, to the best model obtained in a longer period (1).

Unlike humans, Wistar rats have a smooth cerebrum and no foramen of Magendie in the ventricular system. The literature describes environmental effects on rat cerebral anatomy (12, 13). Rodents' large brains are useful in structural and functional neuroimaging studies. Male Wistar rats are superior models in neuroanatomical experiments, especially in behavioral tests originally perfected for this breed (11).

Over time, hybrid imagistic tools, like functional *Positron Emission Tomography (PET)* and structural *Magnetic Resonance Imaging (MRI)* for localization, were developed for *in vivo* studies of neurocognitive disorders (14). A glucose analogue, ^{18}F *fluorodeoxyglucose* (^{18}F*-FDG),* the most widely used radiopharmaceutical in *PET* examinations of *AD*, shows hypometabolism in bilateral temporoparietal regions, precuneus and posterior cingulate regions in humans (15).

Scopolamine (Sco), a cholinergic receptor antagonist, helps induce reversible memory impairment in animals, resembling the cognitive and behavioral deficits of aging or *AD* onset by impairing attention maintenance, information processing, and knowledge acquisition (16).

Considering all the above-mentioned aspects, we aim to understand the framework of neuroanatomy and metabolism of *Sco*-treated rodents. In this article, we bring helpful information in degenerative diseases research, emphasizing on the functional impact of *Sco*-induction correlated with anatomical implications after rat brain removal and tissue dissection.

MATERIAL AND METHODS

Experimental protocols and animal treatments

Adult male Wistar rats (200 ± 8 g) purchased from "Cantacuzino" Institute (Bucharest, Romania), were maintained under controlled conditions: 24 ± 2 ºC, 50 ± 5% humidity, and a 12-hour-light/dark cycle, with *ad libitum* access to tap water and 10g per day standard rodent chow. The animal species and breed were chosen following the indications of Mazen Asaad and Jin Hyung Lee in their guide for studying Alzheimer's disease in animal models (10, 17).

Groups were formed: a *Negative Control group (NG)* received 0.2 mL vehicle (physiological saline), intraperitoneally and another *group(SG)* received 2 mg/kg bodyweight *Sco*, dissolved in 0.2 mL physiological saline, also intraperitoneally, for 28 consecutive days of the experiment.

The Committee on the Ethics of Animal Experiments of the "Grigore T. Popa" University of Medicine and Pharmacy, Iasi, Romania approved the involved protocols (permit number: 38/7.02.2021). All the procedures were in compliance with Directive 2010/63/EU published by the European Parliament and the Council of the European Union on September 22nd, 2010, regarding the protection of animals used for scientific purposes. For this study, we minimized the number of animals used and their potential suffering.

Hybrid PET/MRI cerebral imaging – data acquisition and processing

In the 3rdweek of the experiment, after 15 days of treatment, rats were scanned using a 1 Tesla NanoScan *PET/MRI* system (Mediso, Hungary), dedicated to small animals. The characteristics of this device were previously described (18). A dose of 32.04 ± 6.3 MBq of ^{18}*F-FDG* was injected in a tail vein, allowing the acquisition of *in vivo* hybrid images and metabolic analysis of the cerebral tissue. The animals were kept in a dark room before *Isoflurane* sedation (induction 4%, maintenance 2%). Data acquisition started 30 minutes after radiopharmaceutical administration with an *MRI* scout and an *MRI* localization scan and continued with the *PET* scan, 45 minutes after administration. Animals were deprived of food for about 12-16 hours before the ^{18}*F-FDG* injection. Visual data analysis and quantification were performed using InterView™ FUSION processing software (Mediso, Hungary). The *maximum standardized uptake value (SUVmax)* in g/mL of ^{18}*F-FDG* in cerebral tissue was calculated according to the formula:

$$\text{SUVmax} = \frac{\text{the decay} - \text{corrected maximum activity of tissue volume (Bq/mL)}}{\text{the injected radiotracer dose (Bq)}} * \text{body mass (g)}.$$

Data were collected from 20 specific brain tissue regions, right and left areas: cingulate cortex, entorhinal cortex, retro splenial cortex, temporal association cortex, hippocampal regions (anterodorsally, posterior, poster dorsal, subiculum and ventral) and amygdala, also from cerebellum cortex and the whole brain.

Brain removal and tissue dissection

Inhaled gaseous anesthetics are considered an adequate euthanasia method (19, 20) that we applied after *in vivo* assessments. All rats were terminally anesthetized in a plexiglass chamber, without pain or suffering, using 5% Isoflurane delivered at a rate of 40% volume per minute, to

induce rapid loss of consciousness. In accordance with American Veterinary Medical Association and European Commission guidelines for laboratory animal euthanasia, isoflurane was administered until 15 minutes after the respiratory arrest, then death was confirmed by physical examination (21, 22, 23).

Immediately after euthanasia, the procedure of whole brain collection was accomplished according to the steps described by Parkinson CM, and Kobeissy FH (24, 25). With the rat carcass in ventral recumbency on a clean dissection work surface, scissors and forceps are used to cut the skin over the calvaria along the skull midline. Bilateral cervical skin dissection removes posterior cervical muscles and flips skin over the eyes. The scissors cut the optical nerve beneath the eyes and remove eye bulbs. The midline surface of the skull can be scratched with sharp scissors or a knife, then a blade of small scissors inserted into the foramen magnum cuts the spinal cord below the cerebellum. With the forceps and the inferior blade of scissors inserted into the nasal cavity, both halves of the nasal bones and calvaria can be reflected, exposing the brain. Scissors inserted caudally into the interparietal bone can cut along the sagittal suture through the midline of the bone still holding together to remove occipital bone pieces. Gravity causes brain fallout when the carcass inverts. A curved forceps blade slid under the brain, cerebrum, and cerebellum from the olfactory lobes can pinch any connective tissue or nerves that prevent the brain from falling from the skull. The brain must be rinsed with sterile normal saline buffer and placed on ice to cool down immediately.

After euthanasia, whole brain removal, tissue dissection, probe collection, and labeling required 15-20 minutes per animal. According to the literature, samples were stored at -80°C, before tissue processing (26).

RESULTS

Visual and metabolic analysis

The hybrid ^{18}*F-FDG PET/MRI* imaging technique was used to obtain 160 *MRI* cerebral images and over 800 ^{18}*F-FDG PET* cerebral 2D images in coronal view.

In the first stage, by visual analysis, specific cerebral regions are identified on *MRI* images, like the cerebral cortex, hippocampus, and thalamic area. The *MRI* images did not highlight significant structural differences between the same regions of the two groups. Discreet functional differences are observed in *PET* images from *Sco*-induced brains in comparison with the *NG*. An example of a normal brain *MRI* image and one example of an ^{18}*F-FDG PET* brain image for each group were illustrated (fig. 1). On a gray color scale, brain metabolic activity is normal in the *NG*, represented by a moderate and relatively homogenous whitish-gray cerebral cortex and a homogenous discreetly grayish amygdala and thalamic area. The images of *Sco*-induced brains present homogeneous darker shades of gray in the cerebral cortex, thalamic area, and amygdala.

In the second stage of image analysis, data from the ^{18}*F-FDG PET* scan were expressed in *SUVmax* (g/mL). Overall, from the evaluation of right and left *AD* specific regions, we obtained a metabolic chart (fig. 2) that highlights a global increased metabolic activity in brain tissues of *Sco*-induced rats (a median *SUVmax* = 3.10 g/mL ± 1.13 *standard deviation (SD)*) compared to normal ones (a median *SUVmax* = 1.75 g/mL ± 0.48 *SD*). Also, we identified spike metabolic values (2.5 times bigger) in the amygdala (*SUVmax* = 5.06

g/mL ± 0.21 *SD*) and entorhinal cortex (*SUVmax* = 4.99 g/mL ± 0.11 *SD*) for *Sco*-treated rats, compared to *NG* values (*SUVmax* = 1.88g/mL ± 0.04 *SD*) in the amygdala and respectively (*SUVmax* = 1.88g/mL ± 0.02 *SD*) in the entorhinal cortex. These values exceed *SUVmax* = 3,39 g/mL ± 0.35 *SD*, the value of cerebellum cortex in *Sco*-induced rats. Other regions influenced by *Sco* administration were the subiculum and ventral hippocampus, with values that don't exceed the median value identified in the cerebellum cortex (*SUVmax* = 3.39g/mL ± 0.35 *SD*).

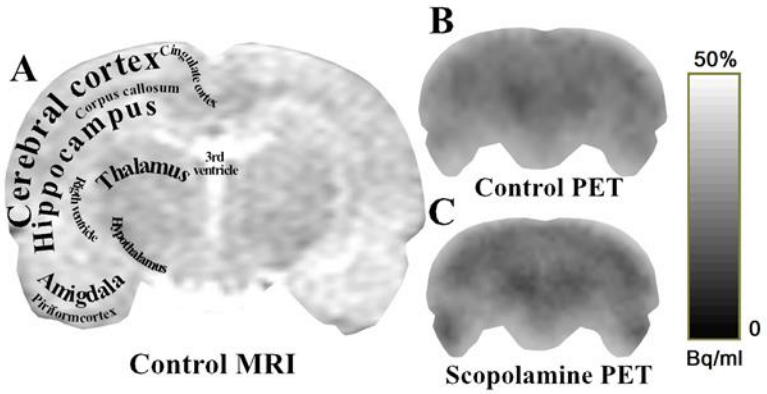

Fig. 1. Representative ^{18}*F-FDG PET/MRI* images of the Wistar rat brain, coronal sections. A, *in vivo MRI* or structural image of a normal rat brain; B, *in vivo PET* or functional image of a normal rat brain and C, *in vivo PET* or functional image of a *Sco*-induced rat brain.

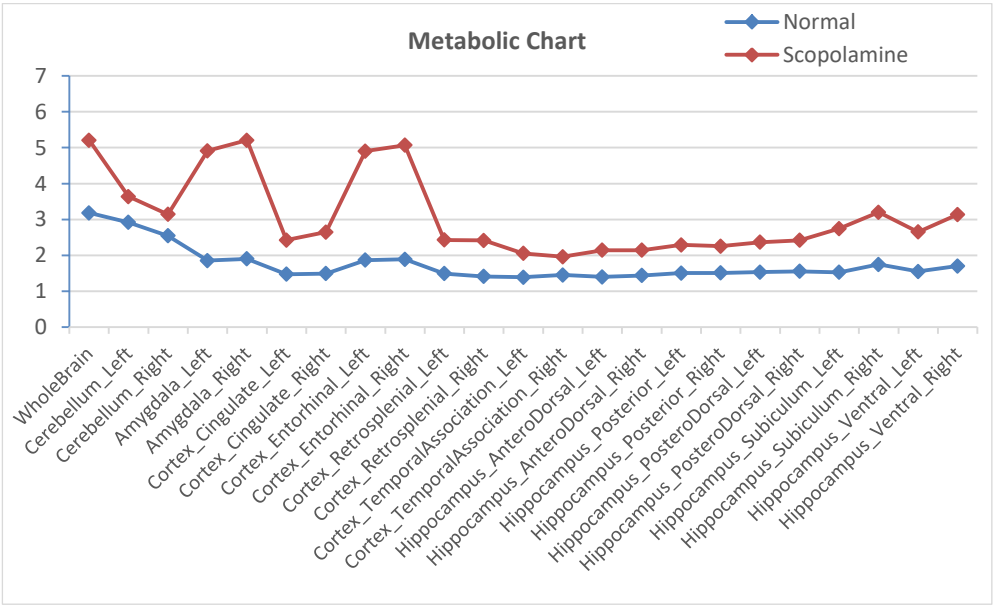

Fig. 2. Scopolamine effects in rat brain regions, compared with normal rats. Results are expressed as *SUVmax* (g/mL) related to body mass.

Brain tissue evaluation

For each rat, 8 different probes were obtained, separately collected and labeled, 4 for each side, right and left: cerebral hemispheres, hippocampus, thalamus, and cerebellum hemispheres. In total, 56 cerebral samples were preserved at low temperatures for homogenization, processing, and further examinations. Brain sections and anatomical regions of a normal Wistar rat from the control group are representative (fig. 3). By macroscopic analysis, no significant anatomic differences were highlighted between the two groups.

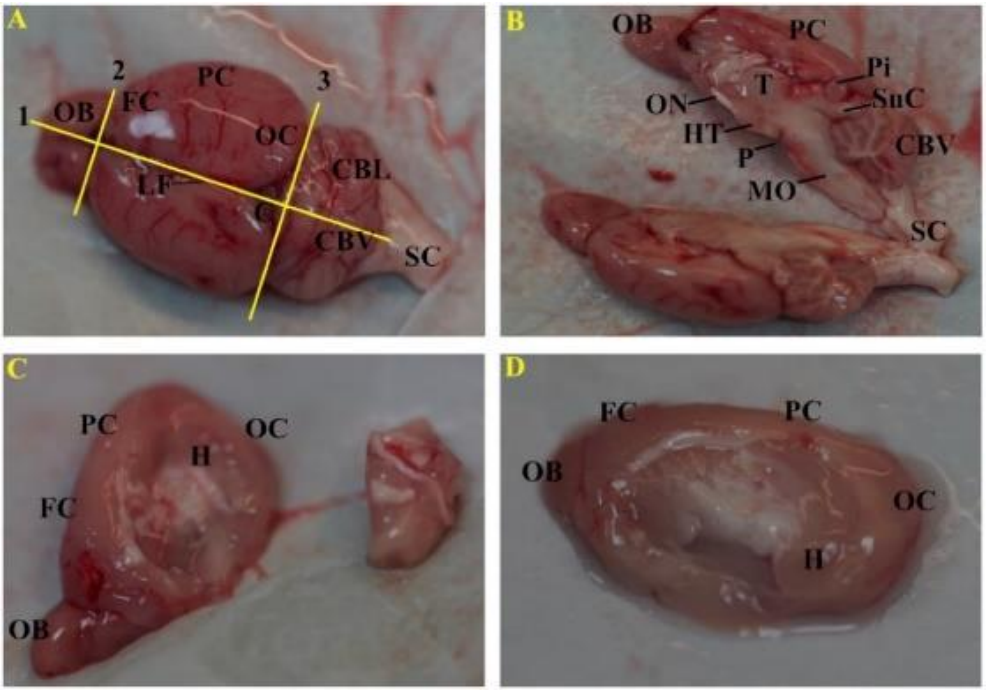

Fig. 3. Major features of the dorsal surfaces and cross sections of a whole brain from a normal Wistar rat (control group). Yellow lines: the number 1 level shown in *A (dorsal surfaces)* corresponds to the *sagittal section* shown in *B, C, and D;* the number 2 level corresponds to the cross-section for olfactory bulb removal; the number 3 level corresponds to the cross-section for cerebellum excision. OB, olfactory bulb; FC, frontal cortex; PC, parietal cortex; OC, occipital cortex; LF, longitudinal fissure; C, rostral and caudal colliculus; CBL, cerebellum-lateral hemisphere; CBV, cerebellum-vermis; SC, spinal cord; Pi, pineal gland; SuC, superior colliculi; ON, optic nerve; T, thalamus; HT, hypothalamus; P, pons; MO, medulla oblongata; H, hippocampus.

DISCUSSION

Sco-induced neurodegeneration in rats includes many karyopyknotic cells, neurons with low tigroid substance staining, increased protein peroxide oxidation, and 2-thiobarbituric acid in the cerebral cortex and hippocampus. Morphological alterations determined by *Sco* initiate along with sleep disorders. In rodents, *Sco* increases non-rapid eye movement sleep, rapid eye movement sleep, and waking electroencephalogram power in the 5.5-10.0 Hz

band. *Sco* also increases regional cerebral glucose metabolism, according to research (27-30). Low doses of anticholinergic drugs can cause non-cognitive effects like increased locomotor activity and increased blood-oxygen level changes in the orbital cortex (31). Long-term *Sco* treatment induces cognitive deficits after the first week, and neurobehavioral changes in rats, including hyperactivity, anxiety-like behavior, and decreased serotonin levels (17, 28). As far as we know, there is only one paper discussing about cerebral rat metabolism related to one dose *Sco*-induction (31), and no article about chronic administration of *Sco*.

In our study, functional ^{18}*F-FDG PET* images show quantifiable brain metabolism changes in *AD*-induced rats compared to the *NG*, even though there are no visible anatomical and structural differences between brain sections and *MRI* images (31, 32). The cerebral metabolism increase is maintained during chronic administration of *Sco*, sparing the cerebellar cortex. Intense metabolism (spike values) is observed in specific *Sco*-treated cerebral regions: the amygdala, with a primary role in the processing of memory decision-making and emotional responses, and the entorhinal cortex, a major player in memory processing of complex associations between experienced events. *Sco* administration discreetly affected the subiculum and ventral hippocampus, reducing hippocampal information sent to the amygdala, with fear conditioning alteration and recent memory deficits in these rats (29, 33, 34). Our study shows that long-term *Sco* treatment increases and maintains metabolic activity in *AD* brain regions. We measured over 100 image slices in both hemispheres for each rat, so data were quantifiable despite small group sizes. Our *AD* animal model study showed that cerebral tissue sampling was simple, fast, and effective if the sampling steps were followed.

Cerebrospinal fluid sampling is a more laborious, demanding, and time-consuming technique, especially for lumbar puncture and it was not discussed in this article.

Without claiming to have found a good *AD* model for reproducing biochemical, histological, and morpho-functional abnormalities of *AD* brain neurodegeneration, nor the best cerebral tissue sampling method, translatability and reproducibility of these techniques are essential keys. Animal research is essential for studying *AD*-specific molecular and cellular processes (1).

CONCLUSIONS

Despite many studies on rat models of *AD*, few describe the methods and necessary steps for brain tissue harvesting and further anatomo-pathological and biochemical analysis.

In conclusion, the anatomical and functional approach of *AD* with drug-induced animals has been shown to be useful in supplementing metabolic data of impaired brain. More precisely, we showed that chronic *Sco* administration maintains quantifiable effects in brain metabolism of *AD*-induced rats (whole cerebral metabolism increase, intense metabolism in amygdala and entorhinal cortex). Our study provides useful information, helps characterization of brain tissues and *AD* physio-pathological mechanisms, improving daily research practice.

ADVANCING PRETERM BIRTH PREDICTION: A PROSPECTIVE MULTICENTRIC STUDY INVESTIGATING THE PREDICTIVE PERFORMANCE OF PARTOSURE, FETAL FIBRONECTIN, AND CERVICAL LENGTH (Abstract): The prediction of preterm birth (PTB) is still a controversial topic, and many efforts have been made to identify the best predictive markers. The **aim** of this study was to prospectively assess the predictive performance of placental alpha macroglobulin-1 (PAMG-1), fetal fibronectin (fFN), and cervical length, both individually and combined, for the prediction of spontaneous preterm birth at 7 and 14 days in a cohort of pregnant patients with threatened preterm labor. **Material and methods:** Between October 2022 and April 2023, we performed a prospective observational study that evaluated 80 pregnant patients with singleton pregnancies, between 24 and 32 completed weeks of gestation. We qualitatively determined PAMG-1 (PartoSure test) and fFN from the vaginal fluid. Clinical data along with cervical length measurements were also retrieved. The predictive performance of the evaluated markers was determined using logistic regression and ROC analysis. **Results:** PartoSure obtained the best results for the prediction of PTB in the next 7 or 14 days. On the other hand, cervical length, at an established cut-off of 19 mm, had the lowest predictive performance for the evaluated outcomes. A combined algorithm that comprised PartoSure, fFN, and cervical length measurements achieved the best predictive performance for the prediction of PTB at 14 days. **Conclusions:** The combined algorithm is superior in terms of predictive performance for the prediction of PTB in the next 7 or 14 days. The PartoSure test could be used individually for the prediction of PTB, but clinicians need to correlate its results with other clinical findings. **Keywords:** PRETERM BIRTH PREDICTION; PARTOSURE; PAMG-1; FETAL FIBRONECTIN; CERVICAL LENGTH.

Preterm birth (PTB), defined as delivery before 37 completed weeks of gestation, is one of the most important public health issues, associated with increased morbidity and mortality rates worldwide (1). According to one of the most recent studies published in the literature, the number of preterm births worldwide declined by 5.26% from 16.06 million in 1990 to 15.22 million in 2019, and the number of fatalities decreased by 47.71% from 1.27 million in 1990 to 0.66 million in 2019 (2).

Even though some significant improvements have been made for the prediction and prevention of this disorder, there is still no accurate test that will correctly identify the majority of patients who will deliver prematurely (3). Maternal risk factors such as personal history of preterm birth, cervical excisional procedures, smoking status, use of assisted reproductive techniques, vaginal and urinary tract infections, thrombotic disorders, or ischemic placental disease have been proposed as predictors of PTB (4-8). Moreover, sonographic markers such as short cervical length, uterocervical angle, uterine artery pulsatility index, as well as cervical and elastography parameters, have proven to be associated with increased risk of preterm birth and adverse pregnancy outcomes (9-12).

Placental alpha macroglobulin-1 (PAMG-1), which is comprised in the PartoSure test, is synthesized by decidual cells that line the uterus and is subsequently released into the amniotic fluid (13). Typically, the concentration of PAMG-1 in vaginal discharge is minimal. However, research has demonstrated that the detection of PAMG-1, either qualitatively or quantitatively, in vaginal discharge is indicative of impending delivery (14, 15).

Fetal fibronectin (fFN) is an important constituent of extracellular matrix, and it is located at the interface between the decidual and chorionic tissues (16). The release of fFN into cervicovaginal secretions occurs as a result of the disruption of the interface caused by inflammation, abruption, or uterine contractions (17). This phenomenon can serve as a foundation for predicting preterm birth.

It is estimated that approximately 65-75% of PTBs occur spontaneously, whereas the remaining cases are iatrogenic in nature (18). The occurrence of spontaneous PTB can be attributed to various pathophysiological mechanisms (19). Consequently, accurately predicting PTB has been a persistent obstacle, given that relying solely on clinical symptoms does not provide sufficient predictive precision (3, 20). In a recent meta-analysis by Melchor *et al.*, PAMG-1, fFN, and cervical length showed a variable predictive performance between studies, due to the influence of demographic and clinical factors (21).

Nikolova *et al.*, comparatively evaluated the predictive performance of PAMG-1, fFN, and cervical length for the prediction of preterm birth in a time-frame between 7-14 days in a cohort of patients 203 patients at risk (22). The authors concluded that PAMG-1 (Sensitivity- Se: 80%; Specificity- Sp: 95%) was the best predictor of PTB within 7 days compared to fFN (Se: 50%; Sp: 72%) and cervical length (Se: 57%; Sp: 73%).

The current literature data is reported heterogeneously, and the predictive performance of combined algorithms was not studied in prospective studies. Therefore, the aim of this multicentric study was to prospectively assess the predictive performance of PAMG-1, fFN, and cervical

length, both individually and combined, for the prediction of spontaneous preterm birth at 7 and 14 days in a cohort of pregnant patients with threatened preterm labor

MATERIAL AND METHODS

We performed a prospective observational study that evaluated pregnant patients with singleton pregnancies, between 24 and 32 completed weeks of gestation who self-reported pelvic pressure, uterine contractions with or without pain, intermittent lower abdominal pain, or any other sign, symptom, or complaint that might be indicative of imminence of preterm birth. Between October 2022 and April 2023, 80 pregnant patients who were evaluated at "Sf. Ioan cel Nou" Emergency Hospital, Suceava, and at "Cuza-Voda" Clinical Hospital of Obstetrics and Gynecology, Iasi, Romania, were enrolled.

Ethical approval for this study was obtained from the Institutional Ethics Committees of "Grigore T. Popa" University of Medicine and Pharmacy Iasi (No. 101/08.07.2021), and "Sf. Ioan cel Nou" Emergency Hospital, Suceava (No. 21/26.10.2022). Informed consent was obtained from all participants included in the study. All methods were conducted in accordance with relevant guidelines and regulations.

The speculum examination of the enrolled individuals revealed that they had cervical dilatation (less than 3 cm) and clinically intact amniotic membranes. Patients with overt fetal membrane rupture, advanced cervical dilatation (more than 3 cm), presence of blood on speculum examination, suspected placenta previa, cervical cerclage in place, patients less than 18 years old, or who were unable to offer their informed consent were excluded from the study.

Complete obstetrical and medical examinations were performed at admission. Before cervical examination, we collected vaginal fluid samples for PartoSure (Germantown, MD 20874, USA), and fetal fibronectin tests (Antagen Pharmaceuticals Inc, Boston, MA 02118, USA). The samples were processed according to the manufacturer's instructions, and both PAMG-1 and fFN were determined qualitatively (test and control line positives). We proceeded with digital and cervical examinations.

The patients underwent standard anatomy scans as well as transvaginal ultrasound performed by experienced obstetricians, with at least level 2 qualification in ultrasound examination, using an E10 scanner with a 4.8 MHz transabdominal probe, and a 5-15 MHz intravaginal probe (GE Medical Systems, Milwaukee, WI, USA).

The following data were recorded: gestational age, clinical symptoms, cervical length, presence of PAMG-1 and fFN, and obstetrical outcomes. The primary outcome was preterm birth in the next 7 days, while the secondary outcome was preterm birth in the next 14 days after admission.

In the first stage of the statistical analysis, descriptive statistics were used for the characterization of our cohort of patients. In the second stage of the analysis, we evaluated and compared the predictive performance of PAMG-1, fFN, and cervical length for the prediction of PTB in a 7-days and 14 time-frames using logistic regression and ROC analysis. Cut-off values, adjusted to gestational age at diagnosis, were identified according to the Youden index. The combined algorithm comprised all three markers and its predictive performance was also calculated. The statistical analyses were performed using *STATA SE*

(version 17, 2022, StataCorp LLC, College Station, TX, USA). A p value less than 0.05 was considered statistically significant.

RESULTS

This study enrolled 80 patients with imminence of preterm birth. Their demographic characteristics are presented in table I. The median age for this cohort of patients was 29.5 years (interquartile range, IQR: 24-35), while the median BMI was 26.43 kg/m^2 (IQR: 22.86- 28.48). The majority of these patients came from a rural background (52.5%), and their clinical characteristics revealed high rates of vaginal infections (22.5%) as well as a significant personal history of preterm birth (17.5%) and other adverse pregnancy outcomes such as preeclampsia and intrauterine growth restriction (13.75%).

The predictive performance of PartoSure, fFN, and cervical length for the prediction of PTB in a 7-days' time-frame was calculated, and it is presented in table II and figure 1. PartoSure obtained the best results when evaluated individually for the prediction of PTB in the next 7 days, with a sensitivity of 71.79%, specificity of 48.78% and an AUC value of 0.602. The combined model achieved a sensitivity of 74.89%, a specificity of 90.24%, and an AUC value of 0.769.

TABLE I.

Demographic and clinical characteristics of patients included in the study

Parameter	Median and IQR or n (%)
Age, years	29.5 (24- 35)
BMI, kg/m^2	26.43 (22.86- 28.48)
Medium	Rural= 42 (52.5%) Urban= 38 (47.5%)
Preterm birth history	14 (17.5%)
Confirmed urinary tract infection	7 (8.75%)
Confirmed vaginal infection	18 (22.5%)
Gestational hypertension	3 (3.75%)
Personal history of adverse pregnancy outcomes	11 (13.75%)
Gestational diabetes	2 (2.5%)
Autoimmune disorders	1 (1.25%)

IQR- interquartile range; BMI-body mass index.

The predictive performance of PartoSure, fFN, and cervical length for the prediction of PTB in a 14-days' time-frame was calculated and it is presented in table III and figure 2. PartoSure obtained the best results when evaluated individually for the prediction of PTB in the next 14 days, with a sensitivity of 53.66%, specificity of 87.18% and an AUC value of 0.704. The combined model achieved a sensitivity of 70.73%, a specificity of 94.87%, and an AUC value of 0.828.

TABLE II.

The predictive performance of individual and combined tests for the prediction of PTB at 7 days.

Test	Sensitivity	Specificity	LR+	LR-	AUC and 95% CI
PartoSure	71.79	48.78	1.40	0.57	0.602 (0.48- 0.70)
fFN	46.15	73.17	1.72	0.73	0.596 (0.48- 0.70)
Cervical length (cut-	38.46	17.07	0.463	3.604	0.204 (0.11- 0.30)
Combined	74.89	90.24	7.35	0.31	0.769 (0.66- 0.86)

LR+- positive likelihood ratio; LR- - negative likelihood ratio;
AUC- area under the receiver operating curve; CI- confidence interval; fFN- fetal fibronectin.

DISCUSSION

The present study evaluated the predictive performance of PartoSure, fFN, and cervical length for the prediction of PTB in a 7-days and 14-days' time-frames. Our results indicated that PartoSure achieved the best results in terms of sensitivity and specificity for the prediction of PTB at both 7 days and 14 days intervals from its detection. Its sensitivity was higher for the evaluated outcome at 7 days, while its specificity increased when used to predict PTB at 14 days. On the other hand, cervical length, at an established cut-off of 19 mm, had the lowest predictive performance for PTB at 7-and 14-days intervals after its measurement.

Our results are similar to those reported in previous literature. Nikolova *et al.*, reported the following sensitivities for PartoSure, fFN, and cervical length for predicting imminent spontaneous PTB within 7 days: 80%, 50%, and 57%, along with their corresponding specificities: 95%, 72%, and 73% (22). Moreover, the authors indicated lower predictive performance of PartoSure (Se- 63%, Sp- 96%), fFN (Se-42%, Sp-72%), and cervical length (Se-54%, Sp-74%) for the prediction of imminent spontaneous PTB within 14 days.

A recent review by Rouholamin *et al.*, indicated that PartoSure test had the highest specificity, positive predictive value (PPV), and positive likelihood ratio (LR+) for the prediction of PTB in all categories of pregnant patients, but, at the same time, outlined the need to correlate its results with the clinical findings and other diagnostic procedures (15).

We also calculated the predictive performance of a combined algorithm that comprised PartoSure, fFN, and cervical length for the prediction of imminent spontaneous PTB within 7 and 14 days. Our results indicated relative similar sensitivities and specificities, although the overall accuracy was higher for the prediction of PTB at 14-days (AUC of combined algorithm: 0.828; 95%CI: 0.72- 0.90). As far as we know, this is the first study in the literature that evaluated the predictive performance of combined algorithms, so comparative data is not available.

PartoSure (PAMG-1) and fFN were both qualitatively determined in our study. Ravi *et al.*, evaluated the predictive performance of various cut-offs of fFN and compared the results with qualitative PAMG-1 for the prediction of PTB in the next 7 to 14 days (23). Their results indicated that PAMG-1 test was the best predictor for the evaluated out-comes, and reported a sensitivity of 67%, and a specificity of 96% for the prediction of PTB in the next 7 days. Moreover, the authors reported that a conventional cut-off for fFN of 50 ng/ml provided enough accuracy for the prediction of the evaluated outcomes (Se- 67%, and Sp-77%).

This study has several limitations: small cohort of patients and qualitative determination of PAMG-1 and fFN. On the other hand, this is the first study that evaluated the predictive performance of a combined algorithm in a prospective setting. Further studies, on larger cohorts of patients, could determine the cost-effectiveness of combined strategies for the prediction of PTB.

CONCLUSIONS

The results of this study indicated that PartoSure achieved the best results in terms of sensitivity and specificity for the prediction of PTB at both 7-days and 14-days intervals from its detection.

On the other hand, cervical length, at an established cut-off of 19 mm, had the lowest predictive performance for PTB at 7-

and 14-days intervals after its measurement.

A combined algorithm that comprised PartoSure, fFN and cervical length measurements achieved the best predictive performance for the prediction of PTB at 14 days.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

CONVENTIONAL VERSUS ENDOVENOUS TREATMENT IN CHRONIC VENOUS DISEASE - A COMPARATIVE STUDY BASED ON QUALITY OF LIFE (Abstract): Chronic venous disease (CVD) modern treatment has to meet efficiency criteria, minimal invasiveness, aesthetical criteria, has to be used in both primary and recurrent treatment and allows the patient to resume normal activities as soon as possible. Alongside the proven effectiveness of the endovascular technique using LASER thermal ablation, a constant concern remains the benefit of improving the patient's quality of life. The patient perceives the aggressiveness of the procedure and the post-procedural recovery differently when treated through conventional method than through endovenous procedures. **Material and methods:** In the present paper we resume a comparison between the surgical treatments of chronic venous disease, conventional versus endovenous LASER thermal ablation. A prospective study was performed on two groups with equal number of patients and similar clinical staging. VEINES and CIVIQ-20 questionnaires were applied pre- and postoperatively (10 days, one month and two months intervals). **Results:** The Global Score Index calculated for all patients preoperatively and postoperatively showed increases in each of the 3 postoperative assessments, proving the therapeutic indication and efficacy of both surgical procedures. **Conclusions:** The recording of higher values for patients treated with endovenous procedure compared to patients treated with the traditional procedure support the hypothesis of this study that quality of life is higher in the group treated with endovenous LASER therapy. **Keywords:** QUESTIONNAIRES, VENOUS DISEASE, CONVENTIONAL VERSUS ENDOVENOUS.

Chronic venous disease (CVD) is a common clinical problem which has a significant impact on patient quality of life (Qol) (1). Reflux in the great saphenous vein (GSV) is the most frequent causes of primary CVD. Saphenofemoral ligation and

stripping of the GSV is considered to be the standard procedure for GSV incompetence with high rate of success and the low rate of recurrence. Although efficient, the conventional procedure is associated with considerable morbidity (2). Among common complications relevant for the impact on the Qol are postoperative pain, paresthesia due to saphenous nerve injury, hematoma and bruising.

Modern CVD treatment must meet several criteria: to be minimally invasive, to be aesthetic, to be effective in the treating the reflux and its consequences, to be effective in recurrences treatment, to allows the resumption of the patient's usual activities in the shortest possible time.

New endovenous procedures have proved their efficacy. Among this procedures endovenous thermal ablation has comparable efficiency with conventional treatment (3, 4, 5).

MATERIAL AND METHODS

The aim of this prospective study was to compare the improvement in Qol in patients undergoing great saphenous vein (GSV) ligation and stripping versus endovenous LASER thermal ablation. Included in this study were 60 patients, divided into 2 equal groups. The patients, with primary varicose veins and GSV incompetence, coming from 2 different vascular surgery units (Department of Vascular Surgery of the Iasi "Sf. Spiridon" County Clinical Emergency Hospital and Epimedica Clinic) were enrolled after informed consent. They already had surgical treatment indication and previously established type of procedure, either endovenous or conventional. Patients underwent Duplex evaluation. Patients with a tortuous GSV or GSV diameter exceeding 10 mm were not included. Each enrolled patient would have been suitable for both procedures and the choice between them belonged to the patient.

The groups included patients with similar demographic (sex distribution, age median, provenience) and medical characteristics (associated pathologies, clinical stages of CVD). All the patients had the same pre- and postoperative recommendations (medication and compressive stockings).

Qol was assessed prior to surgery and for several different intervals over 2 months postoperatively using 2 questionnaires, CIVIQ-20 and VEINES Qol/Sym (6, 7).

CIVIQ-20 questionnaire included 20 questions covering the patient evaluation on 4 aspects: pain characteristics, physical assessment, psychological assessment, social implications. Every item had 5 answer options resulting in 20 items. The final score ranges from 20 to 100 and it is used to calculate an index (GIS index) quantifying the Qol. GIS index stands for: the difference between the final score obtained and the minimum possible score divided by the difference between the maximum possible score and the minimum possible score, all multiplied by 100.

*GIS = 100 - [(final score - 20)/80] * 100*

The other used questionnaire was VEINES Qol/Sym, a specific questionnaire adapted to CVD. This included 26 items regarding CVD symptoms (10 items), CVD related limitations in daily activities (9 items), psychological impact (5 items), assessment of the CVD progression in the last year (1 item), period of the day when the pain intensifies (1 item) (8).

RESULTS

Patient general characteristics are summarized in table I.

Clinical aspects are shown in table II.

TABLE I.

Patient general information

Patient characteristics		Study group (60 ps)	Conventional procedure (30 ps)	Endovenous procedure (30 ps)
Sex				
	M	20%	0%	12 (40%)
	F	80%	30 (100%)	18 (60%)
Age				
	median	51 years	54 years	47 years
Provenience				
	R	24 (40%)	15 (50%)	9 (30%)
	U	36 (60%)	15 (50%)	21 (70%)
Affected lower limb				
	unilateral	33 (55%)	17 (56.67%)	16 (53.33%)
	bilateral	27 (45%)	13 (43.33%)	14 (46.67%)
Previous venotonic medication		45 (75%)	26 (86.66)	16 (53.33%)
Previous compression stockings wearing		35 (58.33%)	14 (46.67%)	11 (36.67%)

TABLE II.

Clinical classification

Clinical classification	Study group (60 ps)	Conventional procedure (30 ps)	Endovenous procedure (30 ps)
C0	0	0	0
C1	0	0	0
C2	9 (15.00%)	3 (10.00%)	6 (20.00%)
C3	31 (51.66 %)	17 (56.67%)	14 (46.67%)
C4	6 (10.00%)	3 (10.00%)	3 (10.00 %)
C5	8 (13.33%)	3 (10.00%)	5 (16.67%)
C6	6 (10.00%)	4 (13.33%)	2 (6.67%)

Majority of patients were female, with unilateral affected limb, in C3 clinical class, previously on venotonic medication (tabs. I, II).

For both groups we evaluated the CIVIQ-20 score and VEINES Qol/Sym at specific periods of time: before the procedure, after the procedure at 10 days, 1 and 2 months. The results are as following.

The average CIVIQ-20 score for the entire lot, calculated to evaluate the Qol before the procedures was 61.19 points. The score evaluated 10 days after the procedures dropped to 53.15, due to postprocedural discomfort. The postprocedural score range was 22.5-96.25 points. The higher the score, the better the patient perceived the Qol. A significant improvement was noticed at 1 and respective 2 months after the procedure (67.44 points, respective 75.59 points) (fig.1).

When we compared the improvement of Qol between groups, we noticed that the average GIS score at each postoperative evaluation timing was higher for the endovenous group (fig. 2). There was no significant difference between the preoperatory evaluation of the groups, certifying the

groups were comparable. Patients had similar perception over the preprocedural Qol. The comparison data that proved to differ significantly between groups were the scores calculated at 30 days and 2 months ($p<0.05$) (tab. III).

Fig. 1. GIS score on the study group

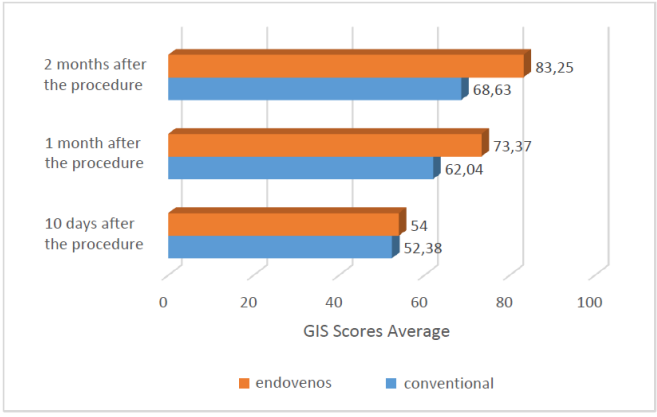

Fig. 2. Comparison between endovenous and conventional average GIS scores

TABLE II.

GIS score comparison between endovenous and conventional

	GIS score before the procedure		GIS score 10 days after the procedure		GIS score 1 month after the procedure		GIS score 1 months after the procedure	
	C	E	C	E	C	E	C	E
Average	55.90	67.00	52.38	54.00	62.04	73.37	68.63	83.25
Standard deviation	22.00	14.90	20.15	18.68	15.36	14.01	14.19	9.32
Maximum score	88.75	96.25	76.25	81.25	80.00	100.00	88.75	100.00
Minimum score	22.50	48.75	8.75	30.00	31.25	51.25	43.75	72.50
Chi test	p=0.098445		p=0.425792		p=0.047343		p=0.006269	

*C=conventional, E=endovenous LASER ablation

Similar to CIVIQ-20 score, the overall analysis of patient responses on VEINES Qol/Sym questionnaire indicates an improvement in postoperative quality of life by achieving higher scores (fig. 3).

The average VEINES Qol/Sym score before the procedures was 54.286 points and remained almost unchanged 10 days after the procedures (55.19 points). After 1 and respective 2 months the scores increased significantly (67.667 points, respective 71.33 points). Endovenous group patients scored higher also in VEINES Qol/Sym ($p<0.05$) (fig. 4).

If we compare the results in both types of questionnaire we find similarities in preprocedural evaluation and the postprocedural data trend (figs. 1, 2, 3, 4).

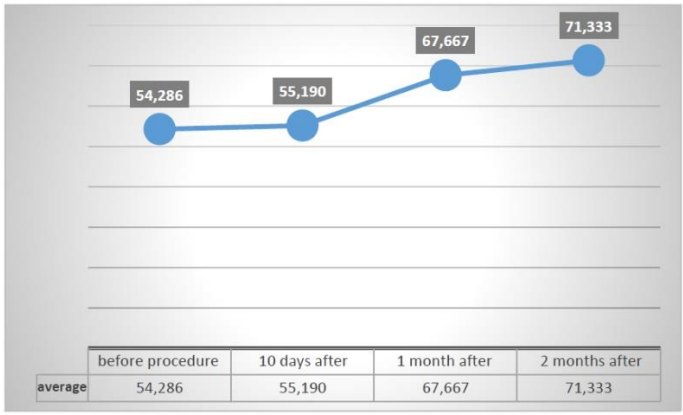

Fig. 3. VEINES Qol/Sym score on the study group

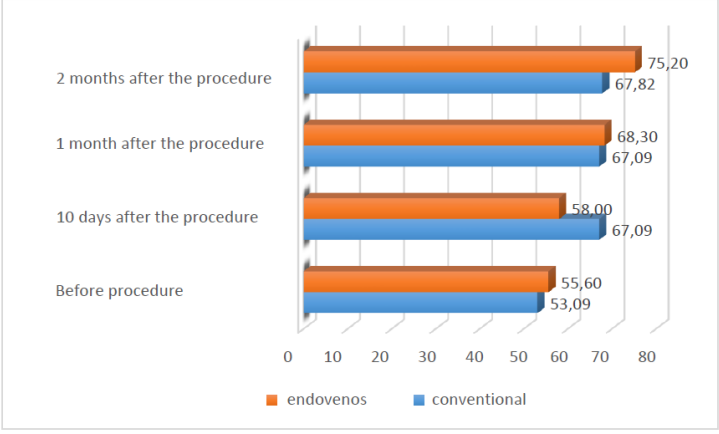

Fig. 4. Average VEINES Qol/Sym score-comparison between endovenous and conventional

DISCUSSION

Enrolling patients both from the private clinic and the hospital allowed us to form 2 comparable groups without taking into consideration the financial aspects that might influence the patients in deciding

between the types of procedures. Patients included in the study had previously established indication of treatment and were suitable for both procedures, conventional or endovenous. Groups characteristics were similar. According to CEAP classification, patient included in clinical class 3 were predominant in both groups.

Lower preoperatively scores are interpreted in the context of CVD symptoms. A correlation between the clinical class and the Qol remain to be investigated. Higher score recorded after any of the procedures prove the efficiency in relieving symptoms for both treatment techniques. A number of studies that refer to patients Qol, including a Cochrane review, concluded that both therapies led to improvement. The present study advocates the same. Recurrence of venous reflux, adverse effects, occurrence of hematomas, neo-vascularization, ulcers, persistence of ecchymosis, recorded lower occurrence rates in patients treated through endovenous therapy (9). This aspect supports the results of the study, which show a significant increase in Qol scores.

Endovenous self-assess higher postoperative scores, with faster reintegration into daily activities is supported through this study and was addressed by several other studies. A retrospective study involving 182 patients who underwent endovenous or conventional surgery, concluded that patients were more satisfied after endovenous procedures. Symptoms of CVD reappeared more often in those who underwent conventional surgery. Also, those who underwent endovenous intervention were shown to have their health condition improved (10).

Evaluating the Qol through questionnaires can be suspected of subjectivity, but by getting similar results through 2 different questionnaires validates the results.

It is important to continue the study after 1 year to see if different perception upon the Qol modifies with time. The presumption is that after a longer period the differences between the 2 procedures are no longer significant.

CONCLUSIONS

CVD is a frequent pathology, with significant impairment on the Qol. Interventions for reflux in the great saphenous vein result in significant clinical improvement, increases the Qol, and may be associated with economic benefits.

In this study, compared CVD treatment procedures proved efficient in improving the Qol. The improvement was obvious and significantly higher in the case of endovenous treated patients in comparison with conventional treated patients. This advocates for better results, with faster recovery, less intense postoperative pain, faster social reintegration for patients treated through endovenous procedure. Conventional surgical treatment is effective and improves the quality of life, but due to the invasiveness of the procedure and the long duration of postoperative recovery, it registers lower postoperative scores

In a rapidly evolving field, non-thermal, non-tumescent options such as mechanochemical ablation or cyanoacrylate adhesive closure are the latest advances and may improve the Qol even more.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

ENDOPHILIN A3 IMMUNOHISTOCHEMICAL HETEROGENEITY IN PANCREATIC DUCTAL ADENOCARCINOMA

Andreea Rusu[1], Ludmila Lozneanu[1], Simona-Eliza Giușcă[1*], Irina-Draga Căruntu[1]

ENDOPHILIN A3 IMMUNOHISTOCHEMICAL HETEROGENEITY IN PANCREATIC DUCTAL ADENOCARCINOMA (abstract): **Background and aim**: Pancreatic ductal adenocarcinoma (PDAC) represents a malignant proliferation with minimally improved survival in last decades that presents systematic changes in classification framework based on new molecular and morphological data. Endophilin A3 (EndoA3), a protein involved in non-conventional endocytosis that was recently integrated in modulation of tumor cell adhesion molecule CD166/ALCAM, has not been evaluated in PDAC. **Materials and methods**: EndoA3 immunoreaction were qualitatively and semi-quantitatively analyzed in 87 cases of PDAC. Statically association between classic PDAC prognostic factors and Endophilin A3 immunohistochemical profile were evaluated. **Results:** Data analysis revealed that EndoA3 immunoprofile is associated with tumor degree of differentiation ($p = 0.01$). For the others microscopic prognostic factors there were no significant statistical correlations. Although not statistically significant, patients with high EndoA3 score presented the lowest survival. **Conclusions**: Endophilin A3 expressed in PDAC presents a cytoplasmic, diffuse or granular, tumor staining, but also a stromal staining. High EndoA3 immunoexpression appears to be associated with a negative prognosis in PDAC. **Keywords**: PANCREATIC DUCTAL ADENOCARCINOMA, ENDOPHILIN A3, IMMUNOHISTOCHEMISTRY.

The histopathological evaluation of pancreatic ductal adenocarcinoma (PDAC) directly impacts on the prognosis. According to the latest World Health Organization (WHO) classification, the confirmed prognostic clinicopathological factors for PDAC are: tumor stage, by tumor size and lymph node invasion, resection margin, degree of differentiation, mitotic index, cellular atypia, lympho-vascular and perineural invasion (1). Additionally, other parameters are also considered as prognostic factors: obesity, race, metastatic location, CA19-9 marker value and SMAD4 gene mutation status (1). Nowadays, the research focused on pancreatic malignant proliferation aims to identify new prognostic and predictive factors, defined histologically and at molecular level. These factors reflect the mechanism of carcinogenesis, being correlated with the progression of pancreatic malignant proliferations (2). Therefore, the prognostic factors panel confirmed by WHO is currently completed by the following histological and serological parameters with prognostic potential:

desmoplastic reaction, tumor budding, circulating tumor cells, Glypican positive exosomes, inflammatory profile - including cytokine levels, microRNA subtypes and non-coding RNA (2).

Endophilin A3 (EndoA3), also called SH3GL3 or EEN, is part of the endophilin family, acting in endocytosis and cell signaling processes (3). In cancer biology, information regarding EndoA3 immunoexpression is conflicting, being associated with negative prognosis in colon carcinogenesis (4), and with favorable prognosis, as a tumor suppressor, in lung cancer (5).

The contribution of clathrin-independent endocytosis in metastatic process particularly involves the migration and invasion step, in connection with retrograde trafficking and cell polarity (6, 7). The EndoA3 mediated endocytosis initiated by Galectin8, that operates through a possible glycolipid-lectin mechanism, represents a method of modulation for tumor marker CD166/ALCAM cell surface expression, consequently interfering with cell adhesion using this non-conventional clathrin-independent pathway (7, 8). In PDAC, the recently described endocytic machinery involvement in cellular trafficking is represented by the clathrin-dependent route, that reports also a potential use for extracellular vesicles as a potential chemotherapeutic transporter (9), without the intervention of the clathrin-independent pathway. In this general context of knowledge, the main stream publications do not include data on the immunoexpression and prognostic role of EndoA3 in pancreatic tumors.

Therefore, our study aimed to investigate the EndoA3 immunoprofile in PDAC, in correlation with the main clinicopathological characteristics and survival.

MATERIALS AND METHODS

The study group comprised 90 patients admitted at the “Sf. Spiridon” County Clinical Emergency Hospital Iasi during a period of ten years (2007-2017), clinically diagnosed with malignant pancreatic tumors. All patients underwent surgical treatment, and the histopathological exam revealed, in 88 cases, a specific morphology sustaining the diagnosis of PDAC. One of these cases was rule out because of partial clinicopathological information. Consequently, our final study group included 87 cases, of which 41 were men (47.13%) and 46 were women (52.87%), with an average age of 60.77 years. The research was approved by the Research Ethics Committees of the “Sf. Spiridon” County Clinical Emergency Hospital Iasi and the “Grigore T. Popa” University of Medicine and Pharmacy of Iasi, respectively.

The retrospective research was based on: (i) the clinicopathological information obtained from the Pathology Department; (ii) the survival data achieved by the clinical follow-up; (iii) the reassessment of all specimens accordingly with the diagnosis criteria recommended by the American Joint Committee of Cancer (10) and the last WHO classification of pancreatic malignancies (1); (iv) the immunohistochemical (IHC) exam for EndoA3 (anti-EndoA3, rabbit polyclonal, PA5-85413, dilution 1/1000, Thermofisher Invitrogen, Waltham, MA, SUA) made on archived paraffin-embedded blocks corresponding to each patient.

Clinicopathologically, the tumor stage was pT1 in 9 patients (10.34%), pT2 in 46 patients (52.87%), pT3 in 30 patients (34.48%), and pT4 in 2 patients (2.29%), the lymph node involvement revealed pN0 in 24 cases (27.58%), pN1 in 43 cases (49.42%)

and pN2 in 20 cases (22.98%), and the TNM stage was established as low for 23 patients (26.43%) and high for 64 patients (73.56%); 19 cases (21.83%) were well-differentiated, 60 cases (68.96%) – moderately differentiated and 8 cases (9.19%) – poorly differentiated; the lympho-vascular invasion was confirmed in 60 cases (68.96%), and the perineural tumor extension was present in 81 cases (93.10%). The clinical follow-up indicated a mean overall survival (OS) of 18.92 months.

The reassessment of specimens allowed us to complete the pathological diagnosis with supplementary data regarding the subtypes and patterns present in each case (11, 12), leading to the following two classifications of cases: conventional PDAC in 57 cases (65.51%) and non-conventional PDAC in 30 cases (34.48%), or glandular PDAC in 50 cases (57.47%) and non-glandular PDAC in 38 cases (43.67%). Several patterns (common in 75 cases, foamy cell in 23 cases, cribriform in 18 cases, large-duct in 12 cases, basal/composite in 13 cases, micropapillary in 7 cases) were identified, defining a homogeneous picture in 40 patients (45.97%) and a heterogeneous one in 47 patients (54.03%).

The IHC exam was validated only for 75 cases. The immunoexpression of EndoA3 was semi-quantitatively evaluated by adapting a scoring system (13), taking into consideration the intensity of immunostaining (I) and the percentage of tumor cells (P). The I assessment led to classification into 4 classes: 0 = no reaction; 1 (+) = weak reaction; 2 (++) = moderate reaction; 3(+++) = strong reaction. For the P assessment, thresholds of 33% and 66% were used, with the following correspondence in the scoring system: 0 = absent; 1-33% = score 1; 34-66% = score 2; 67-100% = score 3. The final score resulted as I x P product, with values between 0 and 9, grouped in the following classes: 0 - negative score; 1-3 – low score; 4-6 – medium score; 7-9 – high score. In addition to this scoring system, EndoA3 immunoexpression was defined as absent (completely negative) and present (not reported at the intensity level).

The statistical analysis was performed for the 75 cases with validated EndoA3 immunoexpression, by using *SPSS version 20* (IBM, Armonk, NY, USA) and Microsoft Excel 2016 (Microsoft, Redmond, WA, USA) and applying χ^2 or Fisher's tests for the clinicopathological correlations, log rank test and Kaplan-Meyer curves for the survival analysis and Cox univariate regression for the prognostic significance.

RESULTS

Qualitative assessment

Comparing the EndoA3 immunoreactivity present in the testis (fig. 1A), used for the validation of IHC exam, with that identified in normal pancreatic parenchyma (fig. 1B), we found acinar immunostaining (cytoplasmic, weak intensity, inconsistent), Langerhans islet immunostaining (cytoplasmic, strong intensity), as well as a positive immunoreaction in intralobular ducts (cytoplasmic, weak intensity, homogeneous). In the medium-sized extralobular ducts we noted a brush-border-like cytoplasmic condensation at the apical domain, of higher intensity than the cytoplasmic one (fig. 1C); the islet of Langerhans showed the highest intensity among the components of the normal pancreatic parenchyma, similar to the intensity of the neuronal bodies from peripheral nervous system (fig. 1B-D).

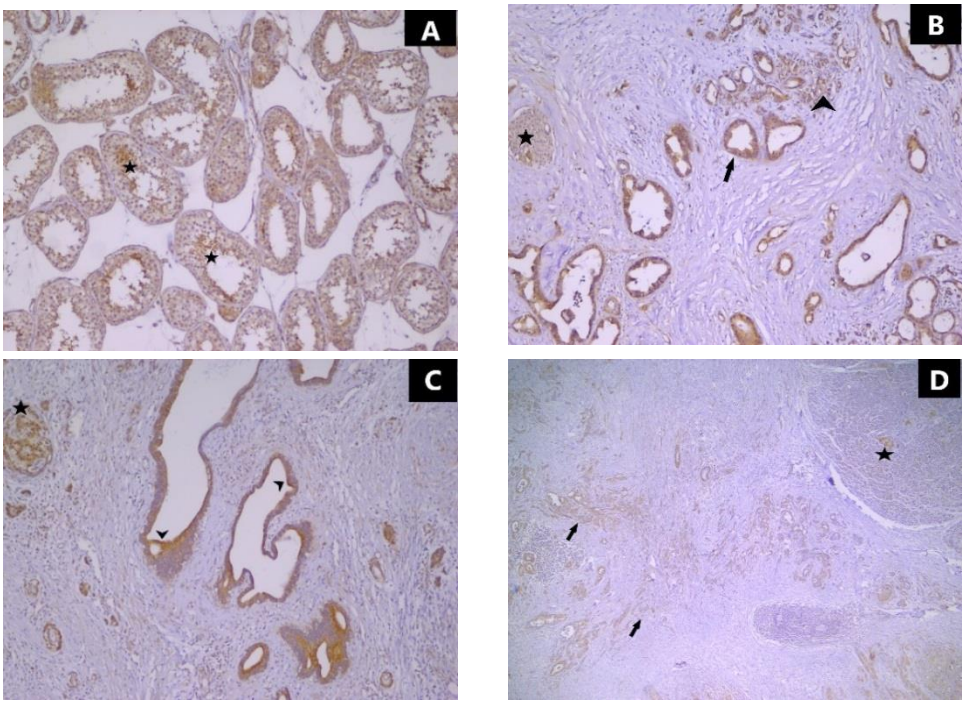

Fig. 1. EndoA3 immunostaining validation elements in testis and pancreatic parenchyma; stars – strong EndoA3 intensity in late spermatids (A), neuronal bodies (B), Langerhans islet (C, D); arrowheads - brush-border-like condensation at the apical domain; arrows – PDAC with homogeneous diffuse strong cytoplasmic EndoA3 immunostaining (B) and heterogeneous cytoplasmic with strong, moderate and weak intensity (D); IHC, anti-EndoA3, x10 (A-C), x4 (D).

The EndoA3 immunoreaction in tumor proliferation was positive in 59 cases (78.66%) and negative in 16 cases (21.33%) (fig. 2A-D). Beside epithelial compartment immuno-reactivity, EndoA3 immunoreaction was identified also in peritumoral stroma (fibroblasts with circular peri glandular distribution) (fig. 2B), being positive in 18 cases (24%), with the following particularities: in two cases, exclusively stromal expression (11.11% cases with stromal expression, 2.66% of the study group), while the other 16 cases presented dual expression, in tumor cells and in peritumoral stroma (88.88% cases with stromal expression, 21.33% of the study group).

The evaluation of EndoA3 in accordance with the histological subtype and morphological patterns identified in ductal proliferations revealed the following aspects: conventional/common areas showed predominantly diffuse, homogeneous (fig. 2A), and focal granular cytoplasmic immunolabeling (fig. 2B); foamy cell and large duct areas were predominantly negative (fig. 2C); cribriform and micropapillary areas showed medium intensity cytoplasmic immunolabeling; poorly differentiated areas showed heterogeneous cytoplasmic immunolabeling (fig. 1D).

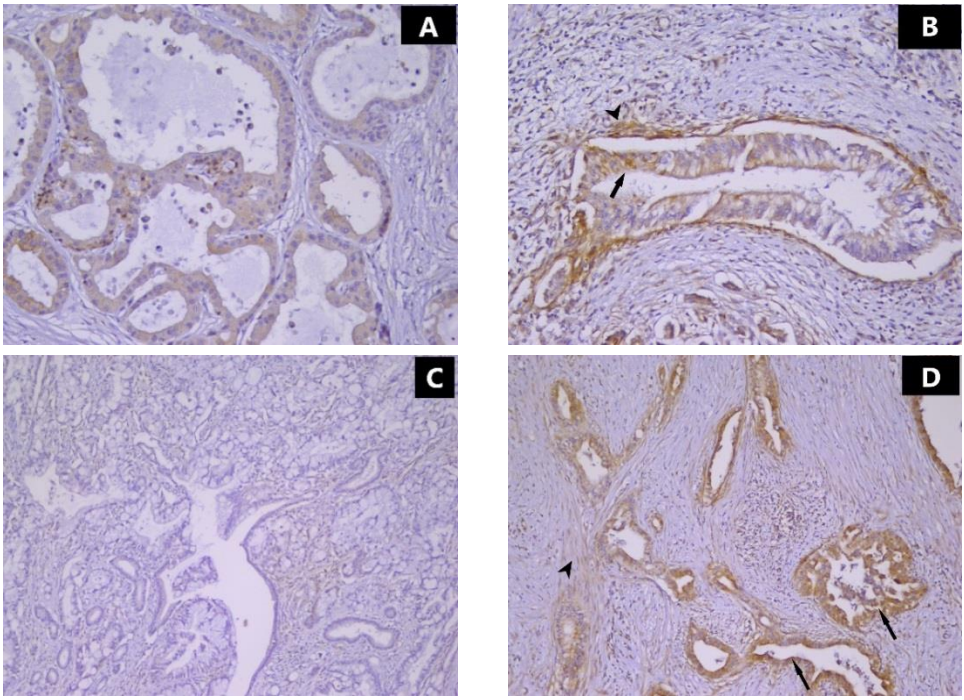

Fig. 2. EndoA3 immunostaining variability in PDAC: tumoral glands – weak diffuse cytoplasmic stain (A), dual stain with stromal – arrowheads, and moderate focal granular cytoplasmic – arrows (B), negative/absent immunoreaction (C), dual stain with stromal weak stromal stain – arrowheads and strong cytoplasmic diffuse and granular stain (D). IHC, anti-EndoA3, x20 (A, B), x10 (C, D).

Evaluation of EndoA3 immunoexpression in lymph node metastases associated with the primary tumor was performed for 36 cases (65.06% of cases with lymph node metastases), being similar to that identified in PDAC.

Semiquantitative assessment

The semiquantitative evaluation of EndoA3, using the scoring system based on immunoreaction intensity (I) and percentage of positive tumor cells (P), led to the stratification into 4 classes of immunoexpression: negative score (16 cases – 21.33%), low score (28 cases - 37.33%), medium score (13 cases – 17.33%) and high score (18 cases – 24%).

Clinicopathological correlations

The statistical analysis revealed statistically significant differences ($p = 0.01$) between the degree of tumor differentiation and EndoA3 profile, defined in 4 classes of immunoexpression by negative score, low score, medium score and high score (tab. I).

Analysis of the degree of tumor differentiation (G) in relation to EndoA3 immunoscore revealed the association between well-differentiated tumors and negative EndoA3 score (8 cases, 50% of well-differentiated tumors), between moderately differentiated tumors and low EndoA3 score (21 cases, 75%), medium EndoA3 score (9 cases, 69.23%) and high EndoA3

score (16 cases, 88.88%).

In addition, considering EndoA3 immunoexpression as absent versus present, statistical analysis also revealed significant association with the tumor differentiation ($p = 0.001$). No statistically significant correlations were obtained for other classical clinicopathological parameters ($p > 0.05$) (tab. I).

TABLE I.

Correlations between clinicopathological features and EndoA3 immunoexpression

Clinical pathological characteristics	EndoA3 #, %				p	EndoA3 #, %		p
	Negative score # total = 16	Low score # total = 28	Medium score # total = 13	High score # total = 18		absent # total = 16	present # total = 59

Low (Ia, Ib, IIa)	5 (31.25%)	8 (28.57%)	3 (23.07%)	1 (5.55%)	0,20	5 (31.25%)	12 (20.33%)	0.35
High (IIb, III, IV	11 (68.75%)	20 (71.42%)	10 (76.92%)	17 (94.44%)		11 (68.75%)	47 (79.66%)	

The mean OS for patients with negative EndoA3 score was 19.56 months, for patients with low EndoA3 score – 21.10 months, for patients with medium EndoA3 score – 22.92 months, and for patients with high EndoA3 score – 13.5 months.

The Kaplan-Meier analysis revealed lack of statistically significant differences between the survival of patients clustered into the 4 score classes ($p = 0.32$) (fig. 3A).

For cases divided according to the absence versus presence of EndoA3 immunoexpression, the mean OS in the EndoA3-negative group was 19.56 months, and for the EndoA3-present group – 19.18 months. The Kaplan-Meier analysis showed also lack of significant differences between survival of patients grouped in relation to EndoA3 immunoreactivity as absent versus present (p = 0.69) (fig. 3B).

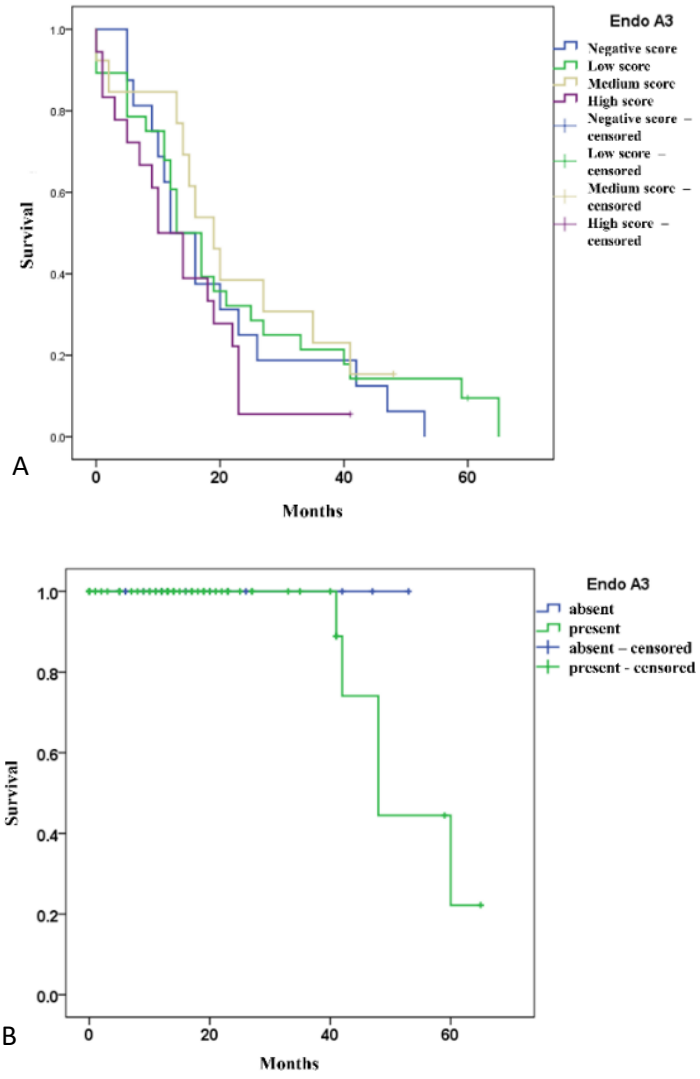

Fig. 3. Kaplan-Meyer survival curves based on EndoA3 immunoexpression assessed semiquantitative (A) and qualitatively (B).

DISCUSSION

Endophilin A3, part of the SH3-domain protein family, was originally described in the brain and testis (3). The endophilin A family includes 3 isoforms, A1, A2 and A3, which are encoded by similar genes and are

associated with the endocytosis process (3, 14). All endophilin isoforms are involved in carcinogenesis, the most studied being A1 and A2 - considered tumor suppressors as they are considerably reduced in metastatic tumors. EndoA3 is the least studied isoform (3). Data available on EndoA3 in the tumoral context reveal different functions depending on the domain involved (4, 5).

In tumor biology, EndoA3 expression has been reported both as a negative prognostic factor (4), being involved in cell proliferation and migration (8, 15), and as a positive prognostic factor, acting as a tumor suppressor, loss of EndoA3 immunoexpression being correlated with advanced tumor stages (5). In oral squamous cell carcinoma, low EndoA3 expression was correlated with the presence of lymph node metastasis (3). EndoA3 involvement in carcinogenesis appears to be dependent on tumor type, with changes at both the gene and protein level (4, 16).

Based on the limited data about the EndoA3 IHC profile in digestive tumor pathology, the relationship between EndoA3 and pancreatic ductal carcinogenesis is being virtually unaddressed. To the best of our knowledge, this is the first study to report EndoA3 immunoexpression pattern and clinicopathological correlations in PDAC.

Subcellular localization for endophilin A indicates cytoplasmic variability with diffuse or punctiform pattern, but also membrane recruitment (3). In colorectal carcinoma, the connection between EndoA3 and endocytic activity analyzed by immunofluorescence revealed a punctiform membrane expression pattern that was associated with the presence of EndoA3 in the cell membrane and was correlated with proliferation process, while the diffuse cytoplasmic expression pattern was associated with loss of EndoA3 from the cell membrane and correlated with a higher cell migration rate (4). In line with this, in our study, we observed heterogeneous immunoexpression in normal pancreatic tissue, with immunolabeling differences in intralobular ducts, which showed homogeneous immunoreactivity of low intensity, whereas in middle extralobular ducts cytoplasmic immunoreactivity was coupled with a brush-border-like condensation at the apical domain, with higher intensity than cytoplasmic. We point out that the standardization of the IHC reaction was performed according to existing literature data on immunolabeling present in testicular germline spermatids (3), in parallel with normal pancreatic tissue resulting internal controls, represented by the islet of Langerhans and neuronal bodies, considered also baseline or standard for the strong intensity of the reaction.

In PDAC, immunolabelling of positive cases (approximately 80% of the study group) was identified both in the epithelial (glandular) component and in the stromal compartment, in the immediate vicinity of the glandular tumor elements. Lymph node metastases showed a similar EndoA3 immunolabel as in the primary tumor, which in our opinion suggests that this molecule does not influence the extent of metastatic process.

At the tumor epithelial compartment level, based on the morphological heterogeneity of PDAC defined by patterns, En-

doA3 immunoexpression was heterogeneous, with subtle subcellular localization characteristics, being identified in homogeneous cytoplasmic variant for cribriform, common conventional or poorly differentiated areas, but also granular or punctiform cytoplasmic variant in common conventional and poorly differentiated areas. Foamy cell and large duct patterns were predominantly negative.

The overlap of EndoA3 immunoexpression with morphological patterns is confirmed by correlation with the degree of tumor differentiation (G), both in the semi-quantitative ($p = 0.01$) and qualitative (present/absent) ($p = 0.001$) assessment variants. According to the obtained results, the absence of Endo A3 is associated with well-differentiated G1 tumors, while the presence, respectively the high EndoA3 score class is associated with less differentiated G2-G3 tumors.

Although associated with tumor grade, a classic prognostic factor in PDAC, in our study EndoA3 immunoexpression was not associated with survival. However, the results for mean OS of patients in relation to semi-quantitative assessment indicate a possible involvement in the development of subtypes with poor prognosis. Patients with high EndoA3 score had the lowest overall survival (13.5 months), patients with negative score had about 5 months longer survival, while patients with low and medium score had better survival, about 9 months longer (22 months). A possible explanation for the lack of significant statistical correlations could be the relatively small number of patients included in the study group unevenly distributed in classes. However, the differences in survival may represent a clue supporting the involvement of EndoA3 in PDAC carcinogenesis, most likely in association with other molecules, possibly the already stated PDAC prognostic marker CD166/ALCAM (17, 18, 19).

CONCLUSIONS

Our study demonstrates the EndoA3 heterogeneity in PDAC, with cytoplasmic, diffuse or granular tumor staining, but also stromal staining. High EndoA3 immunoexpression appears to be associated with a negative prognosis.

EFFICACY AND SAFETY OF EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY (ESWL) IN PIELIC STONES AND INFECTED HYDRONEPHROSIS AFTER DOUBLE-J STENT INSERTION (Abstract): Extracorporeal shockwave lithotripsy (ESWL), along with flexible retrograde ureteroscopy (RIRS), is the treatment of first choice for pelvic stones up to 10 mm, and double-J catheters are not routinely inserted prior to the procedure. However, their insertion is mandatory in patients with infected secondary hydronephrosis. The **aim** of the study was to evaluate the efficacy and safety of ESWL in this particular group of patients compared to patients without double-J ureteral catheters. **Materials and methods:** We conducted a retrospective case-control study of patients with pelvic stones up to 10 mm in whom a double-J ureteral catheter was inserted due to infected hydronephrosis and subsequently underwent ESWL between January 1, 2018 and December 31, 2023. As a control group, we included the patients with pelvic stones without a double-J catheter who underwent ESWL during the same period. We analyzed the demographic data, the stone-free rate and the occurrence of complications in the two patient groups. **Results:** We identified a number of 46 patients with double-J catheters and a number of 118 patients without double-J catheters who underwent ESWL for pelvic stones up to 10 mm. Patients in both groups were over 46 years of age, were predominantly male and had a body mass index (BMI) between 25 and 29.9. There were no statistically significant differences between the 2 groups in terms of stone-free rate, both after the first (78.3% *vs.* 73.7%, p=0.866), second (89.58% *vs.* 89.8%) and third ESWL sessions (93.7% *vs.* 95.7%, p=0.583). The complication rate was reduced in both groups, with no statistically significant differences (14.6% *vs.* 6.77%, p=0.324). **Conclusions:** The presence of double-J ureteral catheters inserted due to infected hydronephrosis did not reduce the efficacy of ESWL in patients with pelvic stones up to 10 mm. In this patient group, ESWL can be recommended as a first-line treatment alongside RIRS. **Keywords:** PIELIC STONES, INFECTED HYDRONEPHROSIS, ESWL, DOUBLE-J STENT SYNDROME.

According to European practice guidelines (1), extracorporeal shock wave lithotripsy and flexible retrograde ureteroscopy are the treatment methods of first choice

for pelvic stones smaller than 10 mm, with an almost stone-free rate of over 90% (2). Some studies show that prior insertion of a double-J catheter before ESWL would reduce the risk of complications (3, 4) or increase the efficacy (5), others show an equal stone-free rate (6) and even a decrease in the efficacy of the procedure (7), both after the first (8) and after several sessions (9, 10), especially for ureteral stones.

In the case of pelvic stones, prior insertion of the double-J catheter is only indicated for large stones (over 2 cm) with post-procedural risk of renal colic, *stein-strasse*, and ureteroscopy (1). Ureteral stenting prior to ESWL is generally contraindicated in patients with pelvic stones smaller than 10 mm, as the stone-free rate in these patients is high (2). In practice, however, some patients with pelvic stones in the pyeloureteral junction or with obstructive ureteral stones present to the emergency room with infected hydronephrosis. Insertion of a double-J catheter is then a necessity to prevent progression of urosepsis and to cure the additional urinary tract infection associated with antibiotic therapy.

After the obstruction and infection are resolved, patients present with localized pelvic stones and a double-J catheter. In this particular case, it is not known whether ESWL can be an alternative to flexible ureteroscopy, as in the case of patients without a double-J catheter. Therefore, we conducted a retrospective comparative study in which we compared the efficacy of ESWL in patients with pelvic stones less than 10 mm without double-J catheters with patients in whom double-J catheters were inserted due to infected hydronephrosis. We mention that in our clinic double-J catheters are not routinely inserted before ESWL to increase the efficiency of the procedure. As a secondary aim of our research, we analyzed the complications that occurred in patients with double-J catheters, especially since in some of them the catheters were inserted over a period of up to 3 months because 2 or even 3 sessions of ESWL were required to achieve stone-free status.

MATERIALS AND METHODS

We conducted a comparative, retrospective study over a 5-year period in patients admitted to Elytis Hospital between January 1st, 2018 and December 31st, 2023 with pelvic stones up to and including 10 mm, with or without double-J catheters, in whom we performed extracorporeal shock wave lithotripsy. The study was approved by the hospital ethics committee. We invite all patients to sign a general consent allowing us to register healthcare data for retrospective studies (laboratory, demographics, therapy and comorbidities). The patients' data were obtained from the observation forms, surgical records and the hospital's electronic registry. Patients were followed until they reached stone-free status or up to one month after the last ESWL session.

The study group consisted of all patients with radiopaque pelvic stones between 5 and 10 mm inclusive who had double-J catheters inserted at least 3 weeks ago, namely 56 patients. All double-J catheters inserted were 7CH, with a length between 24 and 28 cm. We mention that there were 10 patients who originally had ureteral stones and in whom these were pushed back into the renal pelvis by the insertion of the double-J catheter. All patients had negative urine cultures prior to the ESWL procedure.

This explains why the procedure was

performed 3 weeks after insertion of the double-J catheter to allow resolution of the pyelonephritic process. Patients with radiolucent stones, patients with multiple pelvic or pyelocaliceal lithiasis and patients in whom the double-J catheter was inserted because of hyperalgic renal colic or non-functioning kidneys detected by urography or contrast CT were excluded from the study.

Patients with double-J stent syndrome were treated with tolterodine 2 mg twice daily until the catheter was removed. We defined double-J stent syndrome as the presence of lower urinary tract symptoms (LUTS) and/or the presence of macroscopic hematuria. In the absence of improvement of symptoms, flexible retrograde ureteroscopy was proposed to patients and performed, considering the failure of the ESWL procedure, even if the 3 sessions of ESWL were not performed. All patients in this group received prophylactic antibiotic treatment with one tablet of cefuroxime 0.5 g before the procedure.

To form the control group, all patients with pelvic stones between 5 and 10 mm who were treated during the same period were included in the study. This resulted in a total of 126 patients. Patients with secondary 2nd, 3rd and 4th degree hydronephrosis according to the Onen classification (11) and patients with radiolucent pelvic stones were excluded from the study. We excluded patients with significant secondary hydronephrosis because we assumed that obstruction of the pyeloureteral junction may affect the efficacy of the ESWL procedure and because patients in the double-J catheter group did not have this degree of hydronephrosis. We included patients in the study who had secondary 1st grade hydronephrosis because some patients in the study group also had this grade of hydronephrosis.

The ESWL procedure was performed with a Siemens Sonolith device by 3 urologists using the same technique of shock wave application by the ramping method and the same protocol for patient follow-up. Each patient had a maximum of 3 ESWL sessions 4 weeks apart. This interval was chosen to allow for spontaneous elimination of the fragments (12) and recovery of the renal parenchyma after exposure to the shock waves. After each session, the stone-free status was assessed after 4 weeks. In the presence of stones or remaining fragments larger than 4 mm, ESWL procedure was continued.

For fragments less than 4 mm, the double-J catheter was suppressed in the patients in the study group, and the elimination of all fragments was monitored in all patients studied up to an interval of one month. If they had no remaining fragments one month after the last ESWL session, the procedure was considered successful. In the absence of fragmentation or the presence of fragments of any size still present, the procedure was considered a failure and patients underwent an active follow-up program every 6 months.

For all patients in the 2 groups, we collected demographic data and information related to the diagnosis, including age, gender, BMI, location and size of the stones. Their analysis was necessary because we knew that they could influence the stone-free rate of stones, so if there were bias factors in the comparison analyzed. We compared the ESWL parameters, i.e. the number of sessions, the total number of shock waves applied per patient, the average and maximum energy of the shock waves applied and the total energy applied

to each patient regardless of the number of sessions. We analyzed the stone-free rate in the 2 groups, the type of complications and the total number of complications in the 2 groups.

Statistical analysis. Quantitative variables were described by mean and standard deviation and compared using the t-Student test after analyzing the homogeneity of the batches using the Kolmogorov-Smirnov test. Qualitative variables were described by percentages and compared using the chi-square test or the Fischer test if the values of the variables were less than 5. Stone-free rates were compared after each session by calculating the odds ratio and confidence interval.

RESULTS

During the study period, a total of 182 patients with pelvic stones between 5 and 10 mm underwent ESWL. Of these, 56 patients had a double-J catheter and 126 were without a double-J catheter. From the group of patients with double-J catheters, 4 patients with radiolucent stones, 3 patients in whom the double-J catheter was inserted due to hyperalgic renal colic and 3 patients with multiple pyelocaliceal lithiasis were excluded. The result was a number of 46 patients with double-J catheters who formed the study group. Of the 126 patients without double-J catheters, we excluded 3 patients who had concomitant secondary hydronephrosis of the second, third or fourth degree and 5 patients with radiolucent stones. The result was a number of 118 patients without double-J catheters, which constituted the control group.

The demographic characteristics and information on the size and location of the stones are shown in the first table.

TABLE I.
The characteristics of the two groups

		Double-J catheter group (n=46)	Non-Double-J catheter group (n=118)	Statistical test	*p* value
Age, mean ± SD (median/limits)		49.33±15.0 (49/19-79)	46.24±12.59 (45/19-84)	t-Student	0.183
Gender	Male (No., %)	21 (45.7)	67 (56.8)	Chi2	0.201
	Female (No., %)	25 (21.3)	51 (43.2)	Chi2	0.201
BMI	< 24.9	14 (30.4)	14 (11.9)	Chi2	0.005
	25-29.9	29 (63.0)	102 (86.4)	Chi2	0.001
	> 30	3 (6.5)	2 (1.7)	Chi2	0.107
Size of the calculi (mm), mean ± SD (median/limits)		9.22±1.09 (10/6-10)	9.14±1.23 (10/6-10)	t-Student	0.694
	Right side (No., %)	20 (43.5)	59 (50.0)	Chi2	0.452
	Left side (No., %)	26 (56.5)	59 (50.0)	Chi2	0.452

There were no differences between the two groups in terms of average age at the time of ESWL, gender, size and location of the calculi. Regarding BMI, overweight patients were more numerous in the group without double-J catheter (p=0.001). In both groups, the average age was over 46 years, with men predominating and the majority of patients being overweight (63% and 86.4% respectively). The stones were

on average between 9 and 10 mm in size and were predominantly located on the right side in the study group, while they were the same size in the control group, with no significant differences between the two groups (p=0.452)

The parameters of ESWL in the 2 groups are presented in table II.

TABLE II.
The parameters of ESWL in the 2 groups

		Double-J catheter group (n=46)	Non-Double-J catheter group (n=118)	*p* value for t-Student
Mean no. of sessions ± SD (median/limits)		1.26±0.54 (1/1-3)	1.32±0.58 (1/1-3)	0.538
Total no. of shockwaves, Mean ± SD (median/limits)		2218±306 (2300/1180-2626)	2193±409 (2300/765-3203)	0.707
Energy level	Mean, mean ± SD (median/limits)	0.73±0.19 (0.75/0.20-1.10)	0.72±0.21 (0.75/0.25-1.25)	0.699
	Maximum, mean ± SD (median/limits)	1.22±1.29 (1.0/0.50-1.50)	1.02±0.33 (1.0/0.10-2.00)	0.119
Total delivered energy, Mean ± SD (median/limits)		27.36±6.82 (27.82/8.90-47.39)	26.30±8.40 (26.34/3.04-68.00)	0.447

There were no statistically significant differences between the two groups in terms of the average number of sessions required to achieve stone-free status (p=0.538), the total number of shock waves applied (p=0.707), the average and maximum energy levels and the total energy dose (p=0.447). In both groups, between 1 and 2 ESWL sessions were required, over 2000 shock waves, with an average intensity between 0.7 and 0.8 and with a total dose of energy below 30 joules. However, the total dose of applied energy varied in both groups fluctuated in wide intervals, with large differences between minimum and maximum.

The stone-free rate after each ESWL session and the complication rate are presented in table III.

There were no statistically significant differences between the 2 groups in terms of stone-free rate after each of the 3 ESWL sessions. In both groups, the stone-free rate was 70% after the first session, 80% after the second session and 90% after the third session. In the group with double-J catheters, 2 cases developed reflux nephropathy after the second session, necessitating the abandonment of the procedure. In addition, there were 5 cases with double-J stent syndrome, of which 1 case required abandoning the procedure after the first ESWL session. In the group without double-J catheters, there were 6 patients (5.1%) who presented with post-procedural renal colic that responded to analgesic and anti-inflammatory medications and did not require insertion of a double-J stent. In addition, two patients (1.69%) developed infected hydronephrosis after the first session, which necessitated the abandonment of the procedure and insertion of a double-J catheter.

There were no differences in the overall rate of complications between the two groups.

TABLE III.

Stone free rate and the complications incidence in the 2 groups

		Double-J catheter group (n=46)	Non-Double-J catheter group (n=118)	OR C.I.95%	*p* (chi square)
Stone free (No., %)	After 1st session	34 (73.9%)	87 (73.7%)		0.862
	After 2nd session	34+4=38 (82.60%)	87+19=106(89.8%)	0.97 0.32-2.93	0.315
	After 3rd session	38+4 = 42 (91.30%)	106+7=113 (95.7%)	0.66 0.15-2.89	0.269*

DISCUSSION

The results of the study show that ESWL has a similar stone-free rate and the same complication rate for pelvic stones between 5 and 10 mm in patients with double-J catheters inserted for infected hydronephrosis. The main limitations of our study were the retrospective nature and the relatively small number of the study group. The number was limited by the inclusion criteria of patients with infected hydronephrosis due to stones up to 10 mm. A further limitation of the study was the lack of measurement of the density and all 3 dimensions of the stones on native CT, as this is known to influence the rate of fragmentation and elimination of the stones. However, for stones up to 10 mm this has only a minor influence compared to stones over 10 mm.

While in ureteral lithiasis the insertion of a double-J catheter could create an expansion chamber for the fragments that occurred after ESWL (13), in pelvic stones the pyelocaliceal system takes over this role, so that the insertion of the double-J catheter would be useless, there is even the disadvantage of creating an obstacle in the path of the shock waves (13), thus reducing the efficiency of ESWL.

The two study groups had the same values for stone location and size, which allowed comparison of stone-free rates according to the presence or absence of double-J catheters with minimal error factors. In both groups, the age was under 50 years, younger than in other local studies (14), where the average age was over 50 years. This can be explained by the fact that in recent years more and more patients are having routine ultrasound examinations performed, or when symptoms are minimal, which allows diagnosis in the case of some still relatively small stones. As in previous studies, the majority of patients were overweight, with a predominance of males (14).

In both groups, the size of the stones was between 9 and 10 mm, a size at which spontaneous elimination is unlikely. It is likely that many patients with smaller

stones had eliminated the stones spontaneously without the need for ESWL.

If we analyze the stone-free rate in the two groups, we see a good result, the same in both groups as in other studies (15), over 70% even after the first ESWL session, much higher than the rate below 50% in the case of ureteral stones performed with the same technique and device (14). In both groups, the application of the second and third sessions proved useful, increasing the efficiency of the procedure to over 80% and 90%, respectively. Even if we did not obtained results of 98-100% as in flexible retrograde ureteroscopy (RIRS) (2), we consider that the difference of a few percent is not clinically relevant to contraindicate the ESWL procedure, even in patients who wear double-J catheters. In addition, there are patients who do not want surgery and local or general anesthesia, which is necessary to perform RIRS, and who request the non-invasive ESWL procedure, even if stone-free status is achieved faster after RIRS (16). We also see that the presence of the double-J catheters did not lead to an increase but also not to a decrease in stone-free status. We used a combined radiologic and ultrasound guide to focus the calculi, and we changed the position of the patient on the treatment table so that the double-J catheter did not interfere with the stone and shock waves, so that higher energy doses were not required to fragment the calculi in the presence of double-J catheters.

Comparing ESWL parameters, we note that the number of sessions required for ESWL success was low, using lower energy doses than for ureteral stones (14), reducing the risk of renal hematoma, a reducible complication that otherwise did not occur in any treated case.

In terms of complications, although wearing the double-J catheters eliminated the risk of renal colic, it did not reduce the risk of infection. Instead, complications related to the presence of the catheters occurred, such as double-J stent syndrome, which has been reported in high percentages in some studies (17, 18), but only in a low percentage in our study, similar to other local studies (19). However, the presence of double-J stent syndrome could be treated with medication. Only in one case ESWL treatment had to be abandoned, which proves that the presence of double-J stent syndrome does not significantly affect the efficacy of ESWL treatment. It is possible that double-J stent syndrome occurred immediately after catheter insertion, so some of them could not undergo ESWL and opted for RIRS, so the actual number of patients with double-J stent syndrome is higher than reported in our study.

The presence of double-J catheter did not increase the risk of post-procedural infection (20), as reported in some studies (21, 22). There were 2 patients in each group who had high UTIs. Double-J catheter carriers experienced reflux pyelonephritis, which has also been reported in other studies (22, 23), with possible progression to sepsis (22), even in the absence of an obvious inflammatory syndrome (24). This risk was probably reduced in the patients with double-J catheters by the fact that all of them received antibiotic prophylaxis with cefuroxime, one tablet 30-60 minutes before the procedure, and especially because all patients with double-J catheters underwent ESWL 3 weeks after stent insertion for infected hydronephrosis, which allowed the pyelonephritic process to resolve, and also only after a negative urine culture.

The advantage of having double-J catheters in our study, in contrast to other studies (25), was the elimination of the risk of

renal colic and the need to visit an emergency service (26), which can be a problem in patients in remote areas.

The fact that the fragmentation rate was already high after the first procedure made it possible in most cases to remove the double-J stents earlier than 2 months and thus minimize the risk of calcification of the catheters. Although some studies showed a higher recurrence rate in the first 5-10 years after ESWL compared to RIRS (27, 28), we did not find a high rate of residual fragments that would suggest this. In our study group, we found no patients with significant calcifications that required additional maneuvers to remove them, such as endoscopic lithotripsy or retrograde ureteroscopy. Further prospective studies in larger patient groups are needed to validate our results.

CONCLUSIONS

Our study demonstrated that ESWL for pelvic stones up to 10 mm, in patients with double-J catheters inserted for infected hydronephrosis, is a safe and effective method, with minimal side effects, just like ESWL in patients without double-J catheters. In these patients, ESWL can be recommended as a first-line treatment along with RIRS.

CONFLICT OF INTEREST AND FUNDING

Patient consent was obtained for presenting this case in a medical publication to contribute to the expansion of the database on this pathology.

The ethics committee of the medical unit has approved the presentation of the case in a medical article in a medical publication while respecting personal data.

A COMPARISON BETWEEN RISK ASSESSMENT SCORES IN PROSTATE CANCER (Abstract): **Background and aim**: Prostate cancer remains a prevalent cause of malignancy in men worldwide, representing the fifth leading cause of death globally. Oncologic treatment and monitoring of these patients are conducted using multiple scores that assess the risk of biochemical recurrence, with the CAPRA score and D'Amico risk stratification scheme currently being the most widely used. The study aims to compare the prognostic classification of prostate cancer patients using two different scores, identifying similarities and differences that may arise. **Materials and methods:** This retrospective study evaluated both the D'Amico and CAPRA scores in 54 men diagnosed with non-metastatic prostate cancer at the Regional Institute of Oncology between 2017-2021. Transrectal ultrasound-guided biopsy was performed on all patients for diagnostic purposes. The Gleason system was used to grade biopsy cores, and the 8th Edition of AJCC Cancer Staging Manual was used to evaluate clinical stage. **Results:** Following the evaluation of patients with CAPRA scores, out of the total of 54 patients, 12.96% (n=7) had low risk, 42.59% (n=23) had intermediate risk, and 44.44% (n=24) had high risk. Applying the D'Amico score stratified patients into the following risk groups: 5 patients (9.26%) in the low-risk group, 9 patients (16.67%) in the intermediate-risk group, and 40 patients (74.07%) in the high-risk group. In our study, we observed that after overlapping the stratification of patients with the D'Amico and CAPRA scores, out of the seven patients classified as low risk according to the D'Amico stratification, two of them were considered intermediate risk. Furthermore, D'Amico's score considers that out of the 23 patients with intermediate scores, 69.57% (n=16) of them have a high risk. **Conclusions:** The D'Amico stratification tends to categorize patients into a less favorable prognostic group, necessitating a different management approach and active oncological monitoring. On the other hand, the CAPRA score, due to its multitude of composing criteria, individualizes each case, especially for patients classified in the low and intermediate risk groups, thus completing the D'Amico score. Therefore, it beneficial to utilize both scores in evaluating prostate cancer patients for an accurate prognostic assessment. **Keywords**: PROSTATE CANCER, CAPRA SCORE, D'AMICO RISK STRATIFICATION, BIOCHEMICAL RECURRENCE, PREDICTIVE MODELS.

INTRODUCTION

Prostate cancer represents the second most common malignancy in men worldwide, after lung cancer, being the fifth leading cause of death globally (1). The incidence of prostate cancer increases with age (2), and although only one in 350 men under the age of 50 will be diagnosed with this type of cancer (3), in men over 65 years old the incidence rate approaches 60% (4).

Treatment and monitoring of patients depend on the following clinic-pathological parameters found in many models for predicting recurrence after curative treatment: prostate-specific antigen (PSA) level, Gleason score, clinical tumor (cT) stage, various biopsy core characteristics (percentage of positive biopsies), or age (5). Prognostic scores, calculated based on these parameter values, are valuable tools in the oncological approach.

The trend in oncology is to optimize and refine these scores to provide the most accurate assessment of the patient's oncological status and, consequently, optimal therapeutic management. Currently, there are three widely used models (6) to stratify biochemical recurrence after radical prostatectomy: the D'Amico risk stratification scheme (7), the CAPRA score (8), and the Stephenson nomogram (9).

In an attempt to optimize disease progression prediction, in 1998, D'Amico *et al*. developed a combined modality staging system to stratify patients into three risk groups: low, intermediate, or high risk of biochemical recurrence after surgical and radio therapeutic treatment (7). In the D'Amico model, there are three variables categorized as follows: (i) prostate-specific antigen (PSA) levels ≤ 10, 10.1-20, and ≥ 20 ng/mL; (ii) clinical stage categories were cT1/2a, cT2b, and cT2c/T3 or higher; and (iii) biopsy Gleason score categorized as ≤ 6, 7, and ≥ 8.

Several years later, in 2005, the Cancer of the Prostate Risk Assessment (CAPRA) score was published (8). The CAPRA score is based on five variables categorized as follows: (i) PSA levels of ≤ 6, 6.1-10.0, 10.1-20.0, 20.1-30, or ≥ 30 ng/mL; (ii) clinical stage of cT1/2 or cT3; (iii) biopsy Gleason score of no Gleason pattern 4, secondary Gleason pattern 4/5, or primary Gleason pattern 4/5; (iv) age of <50 or ≥ 50 year, and (v) percentage of cancer in the biopsy <34% or ≥ 34%. This score was designed as a predictive stratification tool that could be easily calculated. Subsequently, the CAPRA score was upgraded to the post prostatectomy score (CAPRA-S) and Japanese primary androgen-deprivation therapy (J-CAPRA) (10).

Both the D'Amico and the CAPRA score have been externally validated, and their ability to predict biochemical recurrence has been confirmed over time (11–14).

The aim of our study was to compare the prognostic classification of prostate cancer patients using both the D'Amico score and the CAPRA score to identify similarities and differences that may arise. The analysis of these similarities and differences may lead the oncologist to use one of these two scores in daily practice, considering that it provides beneficial risk stratification for patient monitoring.

MATERIALS AND METHODS

The study population consisted of 54 men diagnosed with prostate cancer (without distant metastases) at the Regional Institute of Oncology between January 1st, 2017, and December 31st, 2021. All patients underwent multicore transrectal ultrasound-guided biopsy for diagnosis. Biopsy cores were graded according to the Gleason system (15). PSA values were measured before digital rectal examination or biopsy. Clinical stage was assigned by the attending urologist / oncologist follow-

ing the American Joint Committee on Cancer TNM guidelines (16, 17). The variables we tracked were: (i) patient age, (ii) PSA value, (iii) Gleason score, (iv) TNM staging and (v) percentage of cancer in the biopsy. All patients were evaluated using both the D'Amico and CAPRA scores, and the results were compared.

RESULTS

The mean age of patients was 68.75 years (range: 48-84 years); one patient was under 50 years old (1.85%) and 53 were over 50 years old (98.15%). The median follow-up time among survivors in our patient cohort was 2 years Out of the 54 patients, 6 (11.11%) registered disease progression and 3(5.56%) have deceased.

In the study group, PSA values were as follows: < 6 ng/mL – 6 patients (11.11%), ≥ 6 – 10 ng/mL – 12 patients (22.22%), ≥ 10 – 20 ng/mL – 22 patients (40.74%), ≥ 20 – 30 ng/mL – 6 patients (11.11%), 8 patients (14.81%) > 30 ng/mL (tab. I).

TABLE I.

Comparison between the distribution of patients according to specific criteria in CAPRA and D'Amico scores

CAPRA score			D'Amico score		
Criteria		Cases # (%)	Criteria		Cases # (%)
Age	<50 y.o.	1 (1.85%)			
	>50 y.o.	53 (98.15%)			
PSA	< 6 ng/mL	6 (11,11%)	PSA	< 10 ng/mL	18 (33.33%)
	≥ 6-10 ng/mL	12 (22.22%)			
	≥ 10-20 ng/mL	22 (40.74%)		10-20 ng/mL	22 (40.74%)
	≥ 20 - 30 ng/mL	6 (11.11%)			
	> 30 ng/mL	8 (14.81%)		>20 ng/mL	14 (25.93%)
Gleason score	4 or 5 patterns	16 (29.63%)	Gleason score	≤ 6	16 (29.63%)
	4 or 5 secondary patterns	22 (40.74%)		7	26 (48.15%)
	4 or 5 primary patterns	16 (29.63%)		≥ 8	12 (22.22%)
Stage	cT1 or cT2	25 (46.30%)	Stage	cT1 – cT2a	5 (9.26%)
				cT2b	12 (22.22%)
	cT3a	29 (53.70%)		≥ cT2c	37 (68.52%)
Cancer in core biopsy	< 34%	16 (29.63%)			
	> 34%	38 (70.37%)			

- number; % - percentage

Gleason scores provided by the histopathological exam of prostate biopsy showed the subsequent distribution: 6 (3 + 3) in 16 patients (29.63%), 7 (3 + 4) in 21 patients (38.89%), 7 (4 + 3) in 5 patients (9.26%), 8 (4 + 4) in4 patients (7.41%), 8 (3 + 5) and 8 (5 + 3) – each in 1 patient (1.85%), 9 (4 + 5) and (5 + 4) – each in 3 patients (5.56%) (tab. I).

The classification/setting of patients in clinical stages revealed: 5 patients (9.26%) in cT1-cT2a, 12 patients (22.22%) in cT2b, 8 patients (14.81%) in cT2c and 29 patients (53.70%) in cT3a (tab. I).

According to the results of the histopathological exam, the percentage of positive cores in prostate biopsy was < 34% in 16 patients (28.63%) and >34% in 38 patients (70.37%) (tab. I).

Based on the evaluated clinical and

pathological parameters, the application of the D'Amico score led to the following patient stratification: 5 patients (9.26%) in the low-risk group, 9 patients (16.67%) in the intermediate-risk group, and 40 patients (74.07%) in the high-risk group. Similarly, following the assessment of patients using the CAPRA score, out of the total of 54 patients, 7 (12.96%) had low risk, 23 (42.59%) had intermediate risk, and 24 (44.44%) had high risk (tab. II).

Interestingly, upon evaluating the same patients using the D'Amico score, out of the 7 patients classified as low risk according to CAPRA score, two of them (28.57%) were considered intermediate risk. Furthermore, the D'Amico score indicated that out of the 23 patients classified as intermediate risk, 16 of them (69.57%) were categorized as high risk. Regarding patients classified as high risk according to the D'Amico classification, all 24 corresponded to the high-risk category in the CAPRA classification (tab. III).

TABLE II.

Distribution of patients in risk groups according to CAPRA and D'Amico scores

CAPRA score			D'Amico score		
Risk	**Score**	**Cases # (%)**	**Risk**	**Score**	**Cases # (%)**
Low	1	3 (5.56%)	low	3	5 (9.26%)
	2	4 (7.41%)			
Intermediate	3	5 (9.26%)	intermediate	4	2 (3.7%)
	4	6 (11.11%)		5	3 (5.56%)
	5	12 (22.22%)		6	4 (7.41%)
High	6	8 (14.81%)	high	5	2 (3.7%)
	7	4 (7.41%)		6	9 (16.67%)
	8	4 (7.41%)		7	14 (25.93%)
	9	3 (5.56%)		8	11 (20.37%)
	10	5 (9.26%)		9	4 (7.41%)

- number; % - percentage

TABLE III.

Differences in distribution of patients in risk groups according to CAPRA and D'Amico scores

CAPRA score		Correspondence to D'Amico score	
Risk group	**# (%)**	**Risk group**	**# (%)**
Low	7 (12.96%)	Low	5 (9.26%)
		Intermediate	2 (3.7%)
Intermediate	23 (42.59%)	Intermediate	7 (12.96%)
		High	16 (29.63%)
High	24 (44.44%)	High	24 (44.44%)

- number; % - percentage

Regarding patient survival, the 3 patients who deceased were categorized in the high-risk group in both the D'Amico score and the CAPRA score (tab. IV). Furthermore, concerning survival without progression, out of the 6 patients who experienced tumor recurrence over a 2-year follow-up period, the CAPRA score classified 2 patients in the intermediate-risk group and 4 in the high-risk group.

On the other hand, the D'Amico score categorized 5 patients in the high-risk group and 1 in the intermediate-risk group (tab. V).

TABLE IV.

Correlation between risk groups in CAPRA and D'Amico scores and overall survival

Overall survival – CAPRA and D'Amico scores				
RISK GROUP	Survival	Death	Survival	Death
	# (%)	# (%)	# (%)	# (%)
	CAPRA SCORE		d'AMICO SCORE	
Low	7 (100%)	0 (0.0%)	5 (100%)	0 (0.0%)
Intermediate	23 (100%)	0 (0.0%)	9 (100%)	0 (0.0%)
High	21 (87.5%)	3 (12.5%)	37 (92.5%)	3 (7.5%)

DISCUSSION

Over time, several studies have demonstrated that the risk of biochemical recurrence after prostate cancer treatment is heterogeneous and depends on factors such as PSA level, clinical stage of the disease, biopsy Gleason score, and characteristics of the core biopsy variables (7–9, 18). Due to this heterogeneity, different authors have proposed various risk classification schemes to quantify the individual rate of biochemical recurrence more accurately after prostate cancer treatment (7–9, 18). In this context, the D'Amico (7) and CAPRA (8) models are the most widely used prediction tools for tumor recurrence risk. However, there have been relatively few studies directly comparing these two stratification models (6, 19).

Among these, the most important are those by Lughezzani *et al.* (19), which directly compare the CAPRA score with the D'Amico risk stratification scheme, and that of Boehm *et al*., which compares the ability of the scores to predict cancer-specific mortality in a large European cohort of patients (6). The study of Lughezzani *et al.* included 1,976 prostate cancer patients treated by open radical prostatectomy. The conclusion was that the CAPRA score outperformed the other scoring models when calibration and decision curve analysis were used as benchmarks (19). Interestingly, they observed that the predictions of the D'Amico model showed limited ability to distinguish high rates of biochemical recurrence in patients. On the other hand, the CAPRA model could discriminate between a much wider varieties of biochemical recurrence risks and showed

the greatest benefit in predicting biochemical recurrence at 3 and 5 years, being the best tool in the cohort (19).

Another study that aimed to identify the most informative prediction tool for cancer-specific mortality was conducted by Boehm *et al.* (6). On a cohort of 2,485 prostate cancer patients who underwent radical prostatectomy, the investigators analyzed three preoperative models (D'Amico, CAPRA, and Stephenson), comparing their ability to predict 10-year cancer-specific mortality. For the 10-year prediction, the CAPRA score showed the highest net benefit. In contrast, the D'Amico model showed underestimation of cancer-specific mortality (6).

In our study we observed that after overlapping the evaluation of patients with the D'Amico and CAPRA scores, out of the 7 patients classified as low risk according to the D'Amico stratification, 2 of them were considered intermediate risk. Furthermore, the D'Amico score categorized 16 (69.57%) out of the 23 patients classified as intermediate risk as high risk. As a result of the overlapping of the two scores, we noticed that the D'Amico risk stratification scheme tends to place patients in a higher risk group.

In our practice as oncologists, we commonly utilize the NCCN (National Comprehensive Cancer Network) guidelines (20), which employ risk prognostic groups ranging from very low to very high (6 groups), as well as the D'Amico classification, for prognostic scoring in prostate cancer. The CAPRA score tends to be more commonly used by urologists, primarily as a prognostic score for patients undergoing surgical intervention for curative purposes. Currently, there is a trend towards a less invasive therapeutic approach, specifically radiotherapy as a method of curative treatment, which is increasingly preferred by patients. As our study results have also shown, the D'Amico stratification tends to categorize patients into a less favorable prognostic group, necessitating a different management approach and active oncological monitoring. On the other hand, the CAPRA score, due to its multitude of composing criteria, individualizes each case, especially for patients classified in the low and intermediate risk groups, thus completing the D'Amico score.

CONCLUSIONS

The assessment of the risk of recurrence should be done on an individual basis, considering the specific characteristics of each patient. The CAPRA score tends to be more comprehensive due to the complexity of the criteria it encompasses, including age (which is absent in the D'Amico score calculation), better stratification of PSA values, and especially the Gleason score, considering each Gleason pattern separately and implicitly each ISUP (International Society of Urological Pathology) prognostic grading group. Therefore, we find it beneficial to utilize both scores in evaluating prostate cancer patients for an accurate prognostic assessment. However, individualization is crucial; placing a patient in a higher prognostic group may benefit them by allowing the application of all necessary therapeutic measures. At the same time, overtreatment should be avoided as much as possible to preserve the patient's quality of life.

REAL LIFE RETROGRADE FLEXIBLE URETEROSCOPY VERSUS EXTRACORPOREAL SHOCK WAVE LITHOTRIPSY IN PYELOCALICEAL STONES UNDER 20MM (Abstract): The **aim** of our study was to highlight groups of patients with single pyelocaliceal stones less than 20 mm in whom flexible retrograde ureterorenoscopy (FURS) or extracorporeal shock wave lithotripsy (ESWL) are superior in terms of stone-free rate and complications. **Materials and methods:** We formed two groups of patients, consisting of patients with single kidney stones under 20 mm in whom FURS was applied (the study group) and another in whom ESWL was performed (the control group). We compared the profile of the patients, the presence of double-J catheters before the procedure, the stone-free rate and the occurrence of complications. **Results:** Patients in the study group were older ($p<0.001$), had larger stones ($p<0.001$) and were more likely to have concomitant diseases ($p<0.001$). The stone-free rate in patients with stones up to 10 mm was similar in both groups (81.25% vs 78.94%, $p=0.777$), while for stones between 11 and 19 mm the stone-free rate was higher in the study group (77.77% vs 45.45%, $p=0.008$). The rate of complications was similar in both groups ($p=0.555$). **Conclusions:** FURS has superior efficacy compared to ESWL in patients with single kidney stones between 11 and 19 mm and similar efficacy in patients with single kidney stones up to 10 mm. The complication rate is low and similar in both groups.
Keywords: FURS, ESWL, STONE-FREE RATE.

According to European guidelines, *flexible retrograde ureterorenoscopy* (FURS) and *extracorporeal shock wave lithotripsy* (ESWL) are the treatment of first choice for single pyelocaliceal stones smaller than 20 mm (1), with the choice of one or the other method being at the discretion of the urologist or the patient, with no clear criteria in favor of one or the other method. In recent years, FURS has taken on an important role alongside ESWL and percutaneous nephrolithotomy (PCNL) among the treatment methods for renoureteral lithiasis (2). However, it has not succeeded in replacing ESWL for stones smaller than 20 mm or PCNL for stones larger than 20 mm

(1). Previous studies have shown that the efficacy of FURS is slightly higher compared to ESWL at over 90% (3, 4, 5) and the complication rate is relatively low for both methods (6, 7, 8). Although there are many studies comparing FURS with ESWL (9, 10, 6), they were performed on homogeneous groups, on selected patients, under ideal conditions, without previous presence of urinary tract obstruction with or without infection, i.e. without possible inflammation in the context, without the presence of ureteral catheters inserted for more than 2 weeks , and without other urological procedures previously performed for the same stones. Also, the surgical limitations due to patients' comorbidities, which can sometimes be important, were not considered when calculating the efficiency of FURS.

Some studies on the efficacy of FURS have focused on the types of lasers used (11) and not on patient characteristics, with the exception of inferior calyx stones, where the infundibulopelvic angle seems to play an important role in the efficacy of FURS (1). For this reason, we conducted a study to determine the efficacy of FURS in terms of stone extraction rate (stone-free rate) and the incidence of complications compared to ESWL under the conditions of daily practice in patients with the above-mentioned characteristics. In this way, we have attempted to specify the indications for the two methods by identifying groups of patients with single pyelocaliceal stones less than 20 mm in which a particular treatment would have a higher success rate and a lower complication rate.

MATERIALS AND METHODS

We conducted a case-control study on patients who underwent FURS for pyelocaliceal stones between 01.04. 2022 and 31.03.2024 at the Urology Clinic of the "Dr. C.I. Parhon" Teaching Hospital in Iasi, Romania, and who constituted the study group. The control group consisted of patients hospitalized at Elytis Hope Hospital in Iasi, Romania, where ESWL was performed for pyolocaliceal stones, between 01.04. 2023-31.03.2024. In this group, we analyzed only the patients who were hospitalized during one year in , as we achieved a ratio of more than one to one compared to the study group. In this way, increasing the number of patients in the control group would not have increased the significance of the statistical tests used. The study was approved by the ethics committees of both hospitals. The patient data were taken from the electronic patient records. We included all patients with pelvic or calyx stones, single, up to 20 mm in size, whether or not they had a double-J ureteral catheter.

We excluded patients under 18 years of age, patients with multiple stones, single stones over 20 mm, stones associated with various renal or pyeloureteral malformations and patients with incomplete data in the electronic registries from the study. Among the patients in the study group, we also excluded patients who underwent FURS due to tumor pathology or exploratory.

The diagnosis of lithiasis was based on an ultrasound examination and a simple kidney X-ray. Computed tomography, which can accurately determine the size of the stones, was not used for diagnosis. We therefore divided the patients into two groups only, according to the size of the stones, and not in many groups, due to relative inaccuracy of the measurement methods. Patients with stones up to and including 10 mm and patients with stones between 11 and 19 mm. When performing

FURS, a 7Ch double J-ureter catheter (24-28 cm) was routinely inserted at least two weeks before the procedure. The reusable flexible ureteroscope (Olympus Comp. Germany) was used. ESWL was performed in the same way by all urologists, using the ramping method, with maximum intensity achieved after a minimum of 500 and a maximum of 3000 shock waves administered. A maximum of 2 procedures were performed one month apart. If fragments of more than 4 mm were still present, the procedure was considered a failure. The Siemens Modulith Lithotripter (Siemens Comp. Germany) was used.

We recorded the demographic data of the patients from the two groups, namely age, sex, location of stones, size of stones, and the presence of comorbidities, DM, obesity, renal failure, anemia, and cardiac diseases such as hypertension and ischemic heart disease. We then comparatively analyzed the frequency and reasons for previous double-J catheter insertion, presence of previous urinary tract infections and type of germs, history of lithiasis, duration of double-J catheter wear until the procedure, and history of urological maneuvers performed for the same stone. In terms of efficacy, we compared the stone-free rate and the occurrence of immediate complications (occurring in the first 7 days after the procedure). These included urinary tract infection, pain and hematuria. We considered "stone-free" status if, after the FURS or ESWL procedure, no remaining fragments were detectable at the 14 day follow-up or if the remaining fragments were less than 4 mm in size, as determined sonographically or radiologically. We considered urinary tract infection if a positive urine culture was highlighted after the procedure, up to 2 weeks, performed after the onset of febrile syndrome or low urinary symptoms. We considered the urine culture positive if more than 10^5 UFC/ml was highlighted in the culture by the qualitative technique.

Of the patients in the study group who were admitted to "Dr. C.I. Parhon" Hospital during the 2-year period, there were 78 patients. Among them, there were 10 patients who underwent FURS for multiple calyceal lithiasis, 4 patients with stones larger than 20 mm, 2 patients with associated renal or pyeloureteral malformations, and one patient who underwent FURS to investigate hematuria diagnosing an upper urothelial tumor. As for the control group, there were a number of 128 patients with kidney stones who underwent ESWL at Elytis Hospital during the above-mentioned period. Of these, we excluded 2 patients under 18 years of age, 4 patients with stones larger than 20 mm, 16 patients with multiple stones and 27 patients with incomplete data in the electronic registries.

Statistical analysis.

The quantitative variables were described by the mean and standard deviation and compared with the t-student test. Due to the large number of patients included in the study, it was not necessary to perform homogeneity tests of the two groups. Qualitative variables were described by percentages and compared using the chi-square test. When we compared qualitative variables that occurred in rare cases (< 5), we applied the Fischer Exact Test for Contingency Table. The data was first entered into an Excel spreadsheet and then transferred to the *SPSS 22.0* program. We considered the difference to be statistically significant if the statistical p-value < 0.05.

RESULTS

During the study periods mentioned, there were 61 patients in the study group who were treated with FURS and 79 patients in the control group who were treated with ESWL. The demographic characteristics of the patients in the 2 groups are listed in first table.

TABLE I.
The characteristics of the 2 groups.

		FURS group (n=61)	ESWL group (n=79)	*p* value chi square
Age (years) mean ± SD		55.87±13.96	46.3±14.66	**<0.001** t-student
Gender	Male (no., %)	21 (34.42%)	47 (59.49%)	**0.003**
	Female (no., %)	40 (65.58%)	32 (40.51%)	**0.003**
Affected kidney	Right kidney	28 (45.9%)	42 (53.16%)	0.394
	Left Kidney	33 (54.1%)	37 (46.84%)	0.394
Stone localization	Pelvis	30 (49.2%)	35 (44.30%)	0.566
	Upper + middle calyx	19 (31.1%)	24 (30.38%)	0.922
	Lower calyx	12 (19.7%)	24 (25.32%)	0.430
Stone size (mm) mean ± SD		13.26±3.84	0.98± 4.82	**<0.001** t-student
≤ 10mm		16 (26.2%)	57 (72.15%)	**<0.001**
11-19 mm		45 (73.8%)	22 (27.85%)	**<0.001**
Comorbidities	Diabetes mellitus (DM)	16 (26.22%)	4 (5.06%)	**<0.001**
	Obesity	18 (29.5%)	10 (12.66%)	**0.013**
	Kidney failure	11 (18.03%)	2 (2.53%)	**0.001** Fisher test
	Anemia	11 (18.03%)	1 (1.26%)	**<0.001** Fisher test
	Heart disease (HBP. ischemic cardiomyopathy)	31 (50.81%)	12 (15.19%)	**<0.001**

The patients in the study group were older ($p<0.001$), the female gender predominated ($p=0.003$) and they had larger stones ($p<0.001$) than the control group. On the other hand, there were no statistically significant differences between the two groups in terms of right/left location ($p=0.394$), pelvic level location ($p=0.566$), upper and middle calyx ($p=0.922$) and lower calyx ($p=0.43$).

In terms of comorbidities, patients in the study group had a statistically significantly higher proportion of DM ($p<0.001$), obesity ($p=0.013$), chronic kidney disease

(p=0.001), anemia (p<0.001), and heart disease (p<0.001).

Table II shows a comparison of the proportion of the presence of preoperative double-J catheter according to their indication and indwelling time, the presence of stones, and the frequency of other urological procedures performed for the same stones that failed to completely solve the stones, requiring FURS or ESWL as a secondary "rescue" treatment for the elimination of remaining stone fragments over 5 mm.

TABLE II.

The presence of double J catheters, history of lithiasis and previous urological procedures for the same stones.

		FURS group (n=61)	ESWL group (n=79)	*p* value for chi-square
Double-J stent inserted for infected hydronephrosis		15 (24.59%)	17 (21.52%)	0.667
Double-J stent inserted for hydronephrosis		35 (57.37%)	5 (6.33%)	**<0.001**
Double-J stent inserted without previous hydronephrosis/infection		10 (16.39%)	0 (0%)	**<0.001** Fisher test
Personal history of lithiasis		30 (49.18%)	14 (17.72%)	**<0.001**
Total nr. of patients with preprocedural double-J catheters		60 (98.5%)	22 (27.85%)	**<0.001**
Preoperatory indwelling time of ureteral double-J catheters	< 1 month	13 (21.31%)	15 (18.99%)	0.733
	1-2 months	18 (29.50%)	7 (8.86%)	**0.001**
	> 2 months	29 (47.54%)	0 (0%)	**<0.001** Fisher test
Interventions after other procedures for the same stone	PCNL	4 (6.56%)	2 (2.53%)	0.402
	URS	11 (18.03%)	2 (2.53%)	**0.002**
	ESWL	6 (9,48%)	0 (0%)	**<0.001**

URS-semirigid retrograde ureteroscopy

Patients in the study group had a higher proportion of double-J catheters inserted preoperatively for hydronephrosis (p<0.001) and to dilate the ureter and facilitate access of the flexible ureteroscope (p<0.001) compared to the control group. They also had a higher proportion of patients with a history of lithiasis (p<0.001), patients in whom the double-J was inserted earlier than two months (p=0.001) and more than 2 months (p<0.001), and more patients who had previously undergone ESWL for the same stone (p<0.001) or semi-rigid retrograde ureteroscopy (p=0.002). On the other hand, there was no statistically significant difference between the two groups in the proportion of patients in whom the double-J catheter had been previously inserted for infected hydronephrosis (p=0.667), in whom the double-J catheter had been inserted earlier than one month preoperatively (0.733) and in patients with a history of PCNL treatment for the same stones (p=0.402).

Table III shows the incidence of urinary tract infections in the two groups, divided by type of germs.

TABLE III.

The frequency of preoperative urinary tract infections by type of germs.

Previous UTIs (No., %)	FURS group (n=61)	ESWL group (n=79)	P Fisher Exact Test for 2x2 Contingency Table
E. coli	9 (14,76%)	2 (2,53%)	**0.010**
P. mirabilis	3 (4,92%)	0 (0%)	0.080
Enterococcus spp.	3 (4,92%)	0 (0%)	0.080
Klebsiella pn.	3 (4,92%)	1 (1,26%)	0.317
S. agalactie	1 (1,63%)	0 (0%)	0.435
P.s aeruginosa	1 (1,63%)	0 (0%)	0.435
Total	20 (32,78%)	3 (3,79%)	**<0.001**

The study group had a higher incidence of preoperative urinary tract infections ($p<0.001$) and urinary tract infections with *E. coli* ($p=0.010$).

For comparisons of stone-free rates in the two groups, including separate comparisons for stones less than 10 mm and greater than 10 mm, as well as the incidence of immediate complications (tab. V).

TABLE IV.

Stone-free rate and the complications incidence in the 2 groups.

		FURS group (n=61)	ESWL group (n=79)	*P* Chi-square
Stone-free		48 (78.69%)	58 (73.41%)	0.47
Stone-free rate for stones ≤ 10mm		13 (81.25%)	48 (78.94%)	0.777
Stone-free rate for stones > 10mm		35 (77.77%)	10 (45.45%)	**0.008**
Complications	Reflux pyelonephritis	2 (3.28%)	1 (1.26%)	0.580 Fisher test
	Clostridium difficile infection	1 (1.63%)	0 (0%)	0.435 Fisher test
	Renal colic	1 (1.63%)	5 (6.32%)	0.232 Fisher test
	Hematuria > 24h	5 (8.19%)	3 (3.79%)	0.295 Fisher test
Total no. of complications		9 (14.75%)	9 (11.39%)	0.555

The overall stone-free rate and the stone-free rate for stones smaller than 10 mm was similar in both groups ($p=0.47$ and $p=0.777$, respectively). However, the stone-free rate for stones larger than 10 mm was higher in the study group than in the control group ($p=0.008$). The incidence of complications was lower in both groups, with no significant differences in any of the complications examined ($p=0.555$). Clostridium difficile digestive infection appeared in one case in the study group.The stone-free rate in patients who underwent FURS surgery was similar regardless of stone size ($p=0.08$), while in the group of patients who underwent ESWL, the stone-

free rate was statistically significantly higher in patients with stones smaller than 10 mm compared to stones larger than 10 mm ($p<0.001$).

DISCUSSION

Our study showed similar efficacy of FURS and ESWL for pyelocaliceal stones up to 10 mm. In contrast, the efficiency of FURS proved to be superior to ESWL for pyelocaliceal stones between 11 and 19 mm. The rate of complications was reduced in both patient groups, with no statistically significant differences.

The main limitation of our study is the retrospective nature and the fact that the procedures were performed by different urologists, leading to some variability in the results, although the same surgical technique was used for FURS and the same method of shock wave administration was used for ESWL.

However, to our knowledge, there is little data in the literature comparing the two procedures and considering special patient groups, such as patients with double J ureteral probes inserted for hyperalgesic renal colic or infected hydronephrosis, as well as patients with comorbidities.

When analyzing the results obtained, we note that the average age of the patients in the study group was higher than in the control group. This could be due to certain treatments of the patients, such as treatment with anticoagulants, which contraindicate ESWL, and perhaps also to the preference of some surgeons who considered a continuous hospitalization in case of FURS to be safer for the patients, as opposed to ESWL, which is performed on an outpatient basis, with the patient being monitored only for a few hours after the procedure and returning for control in a maximum of 2 weeks or in case of complications. We attribute the fact that the female sex predominated in the study group and the male sex in the control group to a coincidence, without a physio pathological explanation.

As was to be expected, the frequency of stones on the right and left side was the same, as there are no anatomical features that lead to an increased frequency on a particular side. The location of stones in the pyelocaliceal system was also similar in both groups, which increases the reliability of the statistical tests, as we know that the stone-free rate is lower for stones in the lower calyx than for stones in the renal pelvis or upper/middle calyx, for both FURS and ESWL.

We found that patients in the FURS-treated group had significantly larger stones than patients in the control group. Stones between 11 and 19 mm predominated, while stones up to 10 mm predominated in the control group. This can be explained by the preferences of the surgeons, who perhaps intuitively recognized that FURS could provide better results compared to ESWL.

As far as comorbidities are concerned, we observe an increased incidence in the study group, which is probably due to the older age. An interesting aspect is that the FURS was performed after the patients had previously been admitted to the emergency room due to recurrent renal colic or infected hydronephrosis and were only later scheduled for FURS. However, due to the large volume of patients in our clinic, they waited over 1-2 months until the procedure, which increases the risk of double-J catheter carriers for the occurrence of urinary tract infections or double-J catheters intolerance. On the other hand, patients for ESWL had no previous emergency room procedures, and they went to an outpatient

ESWL service. The fact that the patients in the study group had larger stones may have caused the more frequent occurrence of complications, obstructions with and without infection.

Another interesting finding of our study was the fact that FURS was performed in a significant percentage as a second-line treatment after the failure of semi-rigid URS or ESWL, whereas the ESWL procedure was predominantly performed as a first-line treatment.

In addition to the prolonged preoperative presence of double-J probes (12), another factor that may have compromised the efficacy of FURS was the presence of urinary tract infections, which can cause inflammation and make advancement of the FURS access sheath difficult. In the case of ESWL, this procedure was performed under ideal conditions, without double-J probes and without preoperative infections. We mention that all ESWL sessions were performed after confirming the absence of UTIs by urine culture, while FURS was also performed during antibiotic treatment for UTIs, without expecting the negative urine culture, which was, however, illusory in the presence of double-J catheters. In contrast to other studies (13, 14), in which many patients did not have double-J catheters in place before the FURS procedure, all but one patient in our study had a stent in place preoperatively. Double J catheters are widely used in urology, not only for drainage of hydronephrosis, but also in open procedures (15, 16), helping to protect the ureter or favoring the healing of some ureteral sutures. However, if you keep them for longer than a month, they can cause irritating urinary tract symptoms (12), which may even require premature suppression.

It is somewhat surprising that the stone-free rate was also below 80% with FURS, not only with ESWL. If ESWL was to be expected according to other studies (17, 18, 19), the lower efficiency of FURS compared to other studies (20) is explained by the fact that it was not performed under ideal conditions, but in patients who had double-J catheters for more than 1-2 months, with associated infections, with comorbidities. Another element to remember is that in 2 patients the technical problems of the equipment forced the abandonment of the procedure, perhaps unjustifiably reducing the efficiency of the method in our study. However, in patients with stones between 11 and 19 mm, the efficiency of FURS was clearly superior, despite all the limitations in terms of patients and equipment.

Compared to other studies (6, 21-23), the rate of complications was reduced in both groups, although there were specific characteristics for each procedure. For example, reflux pyelonephritis and one case of digestive infection with *Clostridium difficile* occurred after FURS, while renal colic occurred after ESWL. Macroscopic hematuria over 24 hours was rare, proving that with adequate technique the risk of hemorrhage is low in both procedures. On the other hand, we had no cases of ureteral lesions or sepsis after FURS, as in other studies (24, 25). The low rate of postoperative infections was consistent with other studies (26), but the development of sepsis should not be neglected (27). The rate of complications in ESWL was also lower in our study than in other studies (23, 28).

Our study is useful for urologists treating such cases as it helps them to make the best decision for the procedure depending on the specifics of the patients and not on

subjective personal preferences.

CONCLUSIONS

FURS and ESWL have equal effectiveness in treating patients with single pyelocaliceal stones up to 10 mm. For patients with single pyelocaliceal stones between 11 and 19 mm, FURS has a superior efficacy. The complication rate is low, both procedures proving high safety. Future prospective studies will be necessary to validate our data.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

VISION AND LIFE QUALITY: A COMPARATIVE ANALYSIS ON ROMANIAN, ENGLISH AND FRENCH STUDENTS FROM MEDICAL UNIVERSITIES (Abstract). Computer Vision Syndrome (*CVS*) is a significant health issue, especially among medical students due to their extensive use of digital devices. This study aims to examine the relationship between *CVS* and the use of various gadgets among Romanian, English, and French medical students, while also assessing differences between these groups. **Materials and methods:** A cross-sectional, questionnaire-based study was conducted with 292 Romanian, 62 English, and 61 French medical students from universities in Iași and Paris. An anonymous survey, distributed via Google Forms, gathered data on *CVS* symptoms. **Results:** Female students predominated across all groups (64.7% of Romanians, 69% of French, and 54.8% of English). The most common eye symptoms reported were dry eyes, focusing difficulties, and eye fatigue. Romanian students experienced dry eyes (73.3%) and blurred vision (68.9%); English students reported eye fatigue (66.1%) and dry eyes (58.1%); while French students primarily faced eye fatigue (91.8%). Neck, shoulder, and back pain were common non-ocular symptoms across all groups. **Conclusions:** Ocular symptoms like dry eyes, eye fatigue, and blurred vision were similar among the groups, with widespread recognition of the health impacts of prolonged screen use. **Keywords:** LIFE QUALITY, VISION QUALITY, STUDENTS, MEDICINE.

INTRODUCTION

Nowadays, the lifestyle has forced the whole world to use modern technology. Smartphones have become so popular that almost all teenagers and adults use them. In the last decade, the social networks and applications have revolutionized the lifestyle of all mankind. Unfortunately, free time is increasingly occupied by the use of various gadgets. Various studies show that the use of gadgets, even for 3 h/day, can represent a health risk of developing Computer Vision Syndrome (*CVS*) (1-3).

Computer vision syndrome also known as digital eye strain (DES), represents a pathology of the modern world characterized by the presence of numerous oculars, musculoskeletal, and behavioral signs and symptoms caused by the prolonged use of electronic devices with digital screens. The first symptoms that appear are: headaches, stinging and redness of the eyes, blurred vision, neck and back pain, eye fatigue, visual accommodation difficulties and

attention disorders (4).

Prevalence of *CVS* ranges from 64% to 90% among computer users (5) and nearly 60 million people suffer from *CVS* globally. Moreover, a million new cases of *CVS* occur each year (1).

Computer Vision Syndrome is a significant health concern, particularly among medical students due to their frequent use of digital devices (4, 6).

This study aims to examine the relationship between *CVS* and gadget usage among Romanian, English, and French medical students, and to identify any differences between these groups.

MATERIALS AND METHODS

Cross-sectional, questionnaire-based study that aims to assess ocular and systemic changes associated with prolonged use of gadgets such as computers, smartphones, laptops and tablets. The anonymous survey was distributed via Google Forms to medical students in Romanian, English, and French. Invitations were sent to students from "Grigore T. Popa" University of Medicine and Pharmacy Iași, Romania, and Sorbonne University Paris 13, France. The survey was available from December 2021 to March 2022. All participants were informed about the study and provided informed consent. The study protocol was approved by the Research Ethics Committee of "Grigore T. Popa" University before enrollment.

The inclusion criteria are represented by the status of a student in a Medical University starting from the 1st year to the 6th year of study. After selection, the following student samples were deemed eligible for analysis:

• 292 Romanian language students from "Grigore T. Popa" University of Medicine and Pharmacy, Iași;

• 62 English language students from "Grigore T. Popa" University of Medicine and Pharmacy, Iasi;

• 61 French students from the Sorbonne University Paris 13.

Participants who did not understand the instructions or did not sign the informed consent form were excluded from the analysis.

The questionnaire entitled "Computer Vision Syndrome" was drafted in Romanian, English and French languages and was published using the Google Forms platform. The survey included 32 questions that collected the following categories of data:

• Socio-demographic data: sex, age, country of origin;

• Data on student status, field and year of study;

• The number of hours spent in front of a digital screen during a 24-hour period;

• Number of hours spent in front of a digital screen separately day and night;

• Data on the type of digital screen devices used and the frequency of their use (PC screen, laptop, tablet, smartphone);

• The degree of brightness of the screen used, the type of ambient light during the use of a digital device and its intensity;

• Ocular and extraocular symptoms noted following the use of a digital screen and their frequency;

• Pre-existing and diagnosed eye pathologies or the use of glasses/contact lenses;

• The purpose for which a medical student predominantly uses a digital screen device;

The data were systematized and centralized in an SPSS 18.0 database and were processed with the statistical functions to

which they lend themselves. Confidence intervals at the 95% significance threshold were used in the data presentation.

For the descriptive statistical analysis, the ANOVA test was used, which highlighted the following indicators:

• primary indicators: minimum, maximum, frequency:

• average value indicators: simple arithmetic mean, median;

• dispersion indicators: standard deviation, standard error, confidence interval of the mean;

• the Skewness test ($-2 < p < 2$) validates the normality of the series of values, it is used when the examined variable has continuous values.

RESULTS

Among French students, 31% were in the 6th year, 28% in the 5th year, 25% in the 4th year, 11% in the 3rd year and 5% were students in the 1st and 2nd year. All French participants were studying general medicine.

Among Romanian students, 44.5% were studying general medicine, 39.1% nursing, 7% dentistry and 4.7% pharmacy and majority of them (44.3%) were in the 2nd and 3rd years of study. Among English students, all of them were in the 5th year and were studying general medicine. In all 3 groups of students, females predominate (64.7% *vs.* 35.3%; p=0.019 – Romanian students, 69% *vs.* 31% - French students, 54.8% *vs.* 45.2%, the ratio being 1.2/1 – English students).

The average daily use of gadgets was 6.18 hours for Romanian students. The average number of hours of use of gadgets during the day was 4.41 hours, and 2.43 hours at night. In the case of English students, the average daily use of gadgets was 5.98 hours. The average number of hours of gadgets use during the day was 3.73 hours, and 2.89 hours at night (tab. I). In the case of French students, the average daily use of gadgets was 6 hours, during the day 4.01 hours, and during the night 2.55 hours.

Compared by gender, it is noted that a higher percentage of males spend more than 5 hours on electronic devices daily than females, for all 3 groups of students

(82.4% *vs.* 78.8% – English students, 75% *vs.* 67 % - French students, 70.8% *vs.* 66.8% - Romanian students).

In the case of all 3 groups, the most used gadgets were smartphones and laptops (figs. 1, 2, 3).

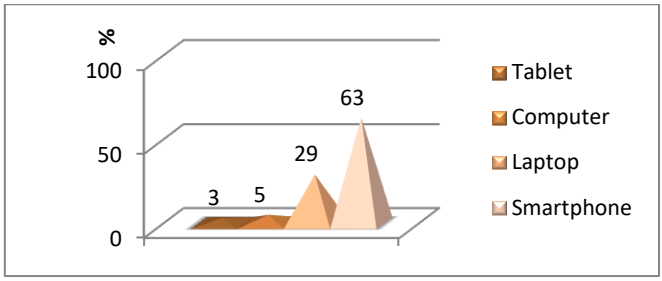

Fig. 1. Frequency of most used gadgets in English students

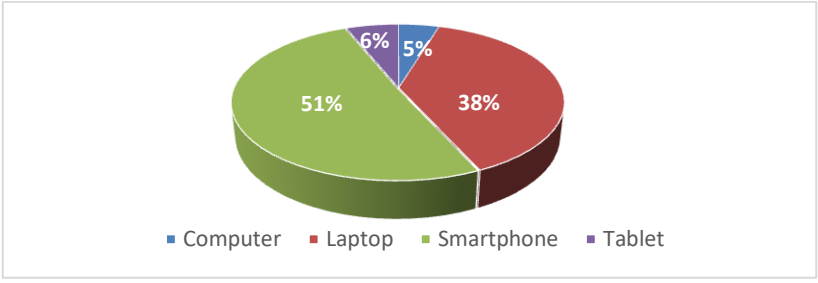

Fig. 2. Frequency of most used gadgets in French students

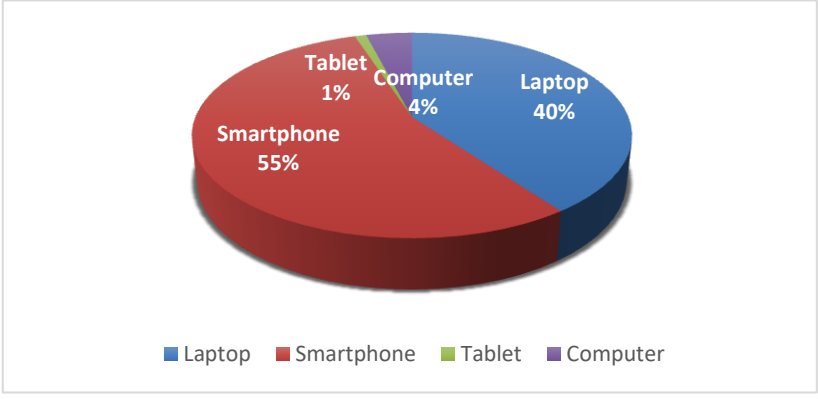

Fig. 3. Frequency of most used gadgets in Romanian students

Out of the total of 292 students from the Romanian language teaching series, 65.4% declared that they wear glasses and 3.9% wear contact lenses. In the case of the 62 medical students in English, 48.8% declared that they wear glasses and 21% wear contact lenses and in the case of the 61 medical students in French, 52% wear glasses and 15% wear contact lenses.

Regarding the most frequently ophthal-

mological symptomatology associated with the prolonged use of electronic devices with digital screens, Romanian language students declared that the most common eye symptoms are dry eyes (73.3%), focusing difficulties (72%), eye fatigue (69.3%), blurred vision (68.9). English language students declared that they most often associate eye fatigue (66.1%) and eye dryness (58.1%), and in the case of French language students, the most common ophthalmological symptoms are eye fatigue (91.8%), blurred vision (34.4%) and dry eyes (34.4%) (fig. 4).

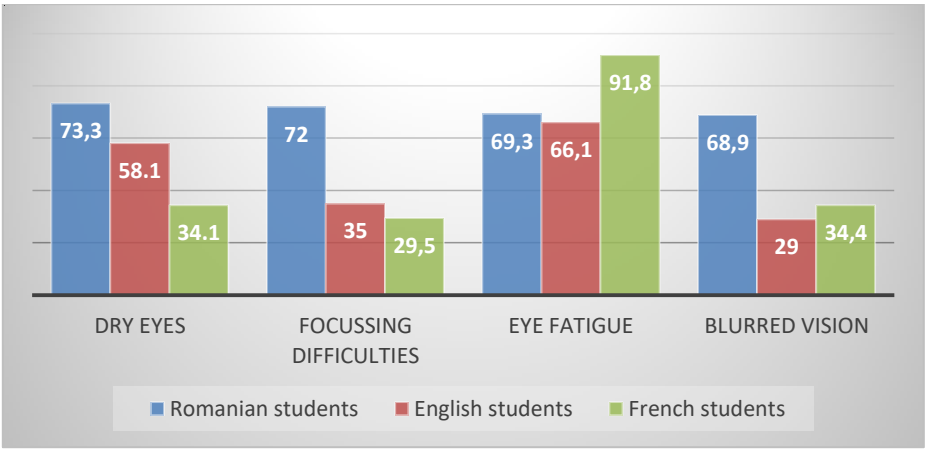

Fig. 4. The frequency of most associated ocular symptoms while using gadgets in all 3 groups of students

Neck, shoulder, and back pain were the most common extraocular symptoms across all groups: 78.7% of Romanian students, about 75% of English students, and 55.1% of French students reported these issues.

There is an awareness of the fact that the use of electronic devices for a long time affects health and lifestyle by all students:

- 229 out of 282 Romanian language students believe that digital screens affect their health and lifestyle;
- 52 out of 62 English language students believe that digital screens affect their health and lifestyle;
- 55 out of 61 French language students believe that digital screens affect their health and lifestyle;

There is also a desire to reduce the time of using electronic devices: 235 out of 282 Romanian students, 50 out of 62 English students and 50 out of 61 French students.

DISCUSSION

It is difficult to find information in the literature about Computer Vision Syndrome among medical students from different languages teaching series or from different universities. A study published in 2021 which used *CVS* Questionnaire in Chinese medical students who took classroom lectures and the same-grade foreign students from a Bachelor of Medicine and Bachelor of Surgery (MBBS) program who took online lectures, showed that online study may increase the risk of *CVS* among university students (7). Another study which was conducted on medical students and employers of College of Health and Medical Technology from province of Al-

Najaf, concluded that there were ocular symptoms in both employers and students (8). Another study analyzed the prevalence of symptoms of *CVS* in students who were studying business and medicine in Saudi Arabia, concluded that the prevalence of *CVS* symptoms was significantly higher among business students (9). Moreover, a recent study conducted on medical students and healthcare workers found that the most common symptoms associated with gadget use were dry eyes found in 73.3% of students, blurred vision in 68.9%, and neck, shoulder and back pain were declared by 65.2% of the students (10). There are also various studies that analyze the effect of *CVS* among medical students, but there is no comparison between *CVS* among medical students from different languages teaching series (11, 12).

Various studies showed that the most used gadget among medical students is the smartphone (13, 14), these results being similar to those of the present study in which the most used gadget was all the smartphone, being used by 55% from Romanian students, 63% from English students and 51% of French students.

In our study, the average daily gadget use was 6.18 hours for Romanian students, 5.98 hours for English students, and 6 hours for French students. These findings are consistent with Ganganahalli *et al.*'s study, which reported average usage of 6.5 hours for males and 6.2 hours for females among medical students in Western Maharashtra, India (15).

Dry eye disease (DED) is a major public health issue that causes visual discomfort and impacts quality of life (16). A study of 100 medical students found dry eyes, blurred vision, and neck, shoulder, and back pain to be the most common symptoms from prolonged screen use (17). Another study on 80 medical students reported headaches in 50% and dry eyes in 45% of participants (18). Similarly, in our study, the most common symptoms among Romanian students were dry eyes (73.3%), focusing difficulties (72%), and blurred vision (68.9%). English students reported eye fatigue (66.1%) and dry eyes (58.1%), while French students mainly experienced eye fatigue (91.8%), blurred vision (34.4%), and dry eyes (34.4%).

A 2022 study on healthcare workers found that prolonged screen time increased the risk of muscle pain, headaches, and stress, highlighting the need to reduce gadget use for doctors and nurses (19). Another 2022 study reported a high prevalence of *CVS* among healthcare workers (20). A study on medical students in Central India showed that 54% had eye-related symptoms, while 46.5% felt anxious or restless without their devices. Common health issues included headaches, back pain, and joint pain (21). In our study, the majority of students, 229 of 282 Romanian, 52 of 62 English, and 55 of 61 French, believed digital screens negatively impacted their health and lifestyle.

Numerous studies have evaluated the disadvantages of *CVS* on health and quality of life. Studies have shown that *CVS* represents a major cause affecting visual function, health and quality of life. Therefore, these studies highlighted that the use of special campaigns and advertisements in schools, universities and mass media are useful and necessary to urge the public to be aware of the risks and disadvantages of *CVS* on health, work and life style (22-25).

In our research, 235 out of 282 (83.33%) Romanian students, 50 out of 62 English students (80.64%) and 50 out of 61

French students (81.96%) are willing to reduce the time spent in front of gadgets. These results are better than those in the study conducted by Gammoh *et al.* which showed that 69.2% of students believe that gadgets affect their health and quality of life, and only 59.2% are willing to reduce time using gadgets (13). Moreover, in the study conducted by Iqbal et al., 76% of the students were willing to decrease their screen hours to avoid *CVS* (17). In our study, more than 80% of the participants are willing to reduce the time spent in front of gadgets, therefore the results of our research being more positive than the two other studies mentioned.

Several limitations should be considered when interpreting the results from our work. The students from English and French series were studying only general medicine, while Romanian students were studying general medicine, nursing, dentistry and pharmacy and therefore the number of Romanian students included in the study was significantly higher than the other 2 groups of students. Moreover, information on *CVS* was obtained through questionnaires, which are not always accurate. Further studies are needed to analyze the effect of gadget use on health and quality of life among medical students and to provide advice and clarification on appropriate gadget use and working time.

CONCLUSIONS

This study's findings, based on questionnaires, reveal that gadgets play a significant role in the daily lives of medical students. Ocular symptoms such as dry eyes, eye fatigue, and blurred vision were common across all three groups. Musculoskeletal issues, including neck, shoulder, and back pain, were also frequently reported. Students in all groups are aware that prolonged gadget use negatively impacts health and lifestyle. Most expressed a willingness to reduce screen time, indicating their recognition of the harmful effects of Computer Vision Syndrome and their desire to improve their quality of life.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

A PRELIMINARY MACHINE LEARNING APPROACH TO UNDERSTANDING THE RELATIONSHIP BETWEEN GLYCEMIC DYSREGULATION, BIOCHEMICAL MARKERS, AND SCHIZOPHRENIA SEVERITY SCORES (Abstract): Schizophrenia is a multifaceted psychiatric disorder associated with significant metabolic disturbances, including glycemic dysregulation and systemic inflammation. This study **aims** to explore the relationship between glycemic control, biochemical markers, and schizophrenia severity using a machine learning approach. **Materials and methods:** A cross-sectional study was conducted on 70 patients diagnosed with schizophrenia, evaluating fasting glucose levels, lipid profiles, inflammatory markers (CRP, ESR), and clinical severity scores (BPRS, PANSS). Statistical and machine learning models, including regression and random forest algorithms, were employed to identify key predictors of psychiatric severity. **Results:** Results indicated that 18.6% of participants exhibited hyperglycemia, which was significantly correlated with higher BPRS and PANSS scores ($p<0.05$). Elevated CRP levels were detected in 45% of participants with moderate-to-severe symptoms, reinforcing the role of systemic inflammation in schizophrenia pathophysiology. Machine learning models identified glycemic status and systemic inflammation as key predictors of psychiatric severity, with behavioral dysregulation strongly linked to hyperglycemia. Furthermore, psychiatric symptom severity was positively associated with metabolic disturbances, particularly among individuals exhibiting irritability and agitation. **Conclusions:** These findings highlight a bidirectional relationship between metabolic dysfunction and schizophrenia severity, suggesting that glycemic control and inflammation may serve as important clinical biomarkers. The integration of machine learning techniques offers a novel approach to identifying metabolic predictors of psychiatric severity, potentially informing personalized treatment strategies. **Keywords:** SCHIZOPHRENIA, PSYCHOTIC DISORDER, METABOLIC DYS-REGULATION, GLYCEMIC VARIATIONS, BPRS, MACHINE LEARNING, AI TECHNIQUES.

INTRODUCTION

Schizophrenia (SCZ) is a complex neuropsychiatric disorder characterized by cognitive, emotional, and behavioral dysfunction. Despite extensive research, its pathophysiology remains incompletely understood, with growing evidence highlighting a crucial link between metabolic

dysregulation and symptom severity (1, 2). Glycemic abnormalities, including insulin resistance and hyperglycemia, are disproportionately prevalent among individuals with schizophrenia, independent of antipsychotic treatment (3, 4). Patients with schizophrenia have a two- to threefold increased risk of developing type 2 diabetes, suggesting an intrinsic metabolic vulnerability mediated by hypothalamic-pituitary-adrenal (HPA) axis dysfunction, chronic inflammation, and oxidative stress (4, 5, 6).

Emerging studies indicate that metabolic disturbances may exacerbate psychiatric symptoms. Elevated fasting glucose levels and insulin resistance have been linked to increased symptom severity, cognitive impairment, and poor treatment response (7, 8). Chronic hyperglycemia and neuroinflammation may alter brain function through mechanisms such as vascular damage, impaired neurotransmission, and oxidative stress, potentially worsening psychotic symptoms (9, 10). Furthermore, systemic inflammation, marked by elevated C-reactive protein (CRP) and interleukin-6 (IL-6), is commonly observed in schizophrenia and correlates with both metabolic syndrome and psychiatric burden (11, 12, 13).

The rapid advancement of machine learning (ML) techniques has opened new avenues for analyzing complex relationships between metabolic biomarkers and psychiatric symptoms. ML models can identify nonlinear patterns in biochemical and clinical data, potentially enhancing our understanding of metabolic contributions to schizophrenia severity (14, 15). However, research integrating ML with biochemical markers and psychiatric scales remains limited.

This study aims to explore the relationship between glycemic dysregulation, biochemical markers, and schizophrenia severity using a preliminary machine learning approach. Specifically, we seek to identify key metabolic markers associated with psychiatric symptom severity using clinical scales such as the Brief Psychiatric Rating Scale (BPRS) and the Positive and Negative Syndrome Scale (PANSS), while developing and testing machine learning models to predict schizophrenia severity based on biochemical and psychometric data. By integrating biochemical assessments with advanced data analytics, this research contributes to precision psychiatry by investigating metabolic predictors that could inform individualized treatment strategies, ultimately improving clinical outcomes for individuals with schizophrenia.

MATERIALS AND METHODS

Study design. This study utilized a cross-sectional design to examine the relationship between glycemic dysregulation, other biochemical parameters, and schizophrenia symptom severity. Data were collected from patients diagnosed with schizophrenia or psychotic disorders according to ICD-10 criteria at the largest psychiatric hospital in northeastern Romania. Ethical approval was secured from the institutional review board, and all participants provided written informed consent prior to enrollment.

Participants. A total of 70 adult participants (18–65 years old) with a confirmed schizophrenia or psychotic disorder diagnosis were included. Inclusion criteria required recent biochemical profiles and willingness to participate. Exclusion criteria comprised comorbid neurological or metabolic disorders unrelated to schizo-

phrenia, current substance use disorders, and history of traumatic brain injury. Clinical severity was assessed using the Brief Psychiatric Rating Scale (BPRS) and the Positive and Negative Syndrome Scale (PANSS), ensuring standardized evaluation. Sociodemographic data, including age, gender, and residential background, were collected for context.

Data collection. Biochemical assessments were performed using fasting blood samples to measure glucose levels, lipid profiles (HDL, LDL, triglycerides), and inflammatory markers (C-reactive protein [CRP] and erythrocyte sedimentation rate [ESR]). Psychiatric symptom severity was evaluated with the BPRS and PANSS scales, administered by trained clinicians to ensure reliability. Anthropometric measurements (weight, height, waist circumference) were recorded to calculate body mass index (BMI), following World Health Organization (WHO) guidelines.

Statistical analysis. Data integrity was ensured by handling missing values through multiple imputation and excluding clinically irrelevant outliers. Pearson's and Spearman's correlation analyses were applied to examine relationships between biochemical markers and psychiatric severity scores. Regression models were utilized to identify predictors of glycemic levels and their association with symptom severity.

For machine learning analysis, models including random forest regression and support vector machines (SVM) were implemented to identify nonlinear relationships between biochemical and psychometric data. Performance was evaluated using R-squared (R^2), root-mean-square error (RMSE), and mean absolute error (MAE). K-fold cross-validation was applied to enhance generalizability, and feature importance rankings were generated to highlight the most significant predictors.

Ethical considerations. The study adhered to the principles of the Declaration of Helsinki, ensuring the ethical treatment of all participants. Data confidentiality was maintained by anonymizing all identifying information. Participants retained the right to withdraw from the study at any time without consequence.

RESULTS

Participant characteristics

The study included 70 participants diagnosed with schizophrenia, evenly distributed across age and gender categories. The cohort consisted of 40 males (57.1%) and 30 females (42.9%), with a balanced representation of urban (57.1%) and rural (42.9%) backgrounds. Participants had varying educational and occupational statuses, reflecting a heterogeneous sample.

Glycemic and metabolic profiles

Biochemical assessments revealed a high prevalence of metabolic disturbances. Hyperglycemia was observed in 18.6% of participants, while 81.4% had normal fasting glucose levels. Body mass index (BMI) analysis showed that 47.1% were overweight or obese, with 37 participants classified as normal weight, 22 as overweight, and 11 as obese. Dyslipidemia, including hypercholesterolemia (20%) and hypertriglyceridemia (10%), was present in a significant subset of patients.

Inflammatory markers were elevated in a large proportion of participants. CRP levels above 10 mg/L were found in 45% of participants, and elevated erythrocyte sedimentation rate (ESR) was detected in 60%, supporting previous findings on the inflammatory component of schizophrenia.

Behavioral dysregulation cluster

Behavioral symptoms such as irritability, dysphoric mood, agitation, and reduced frustration tolerance were among the most prevalent and clinically impactful features within the cohort. Irritability was observed in 61.4% of participants, making it the most frequently reported behavioral symptom, followed by agitation, which had an incidence rate of 17.1% over a 12-month period.

The relationship between behavioral dysregulation and metabolic disturbances was striking. Individuals with irritability were nearly five times more likely to experience hyperglycemia compared to those without this symptom, with a relative risk (RR) of 4.72. The odds ratio (OR) further highlighted the strength of this association, showing that participants with irritability had a 6.75-fold higher likelihood of hyperglycemia (fig. 1). From a diagnostic perspective, the sensitivity of irritability as a predictor of hyperglycemia was exceptionally high at 88.2%, though its specificity was moderate at 47.2%. This indicates that while irritability effectively identifies cases of hyperglycemia, it may also yield false positives among those without metabolic disturbances.

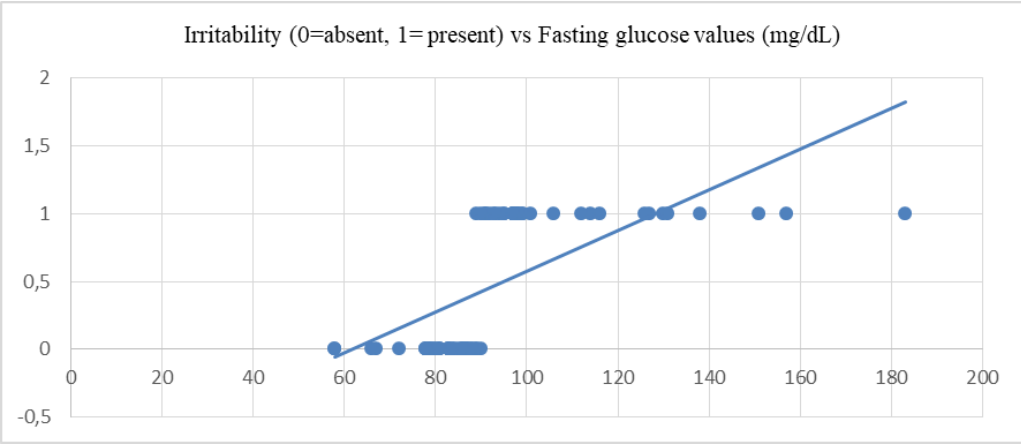

Fig. 1. Correlation graph between Irritability and Fasting glucose values (mg/dL)

Elevated inflammatory markers further linked behavioral symptoms to metabolic dysregulation. Participants with irritability frequently exhibited C-reactive protein (CRP) levels above 10 mg/L (45%), reinforcing the role of systemic inflammation in the pathophysiology of this cluster. Neuroinflammatory processes likely activate the hypothalamic-pituitary-adrenal (HPA) axis, contributing to both psychiatric and glycemic disturbances. Moreover, CRP and leukocytosis collectively explained 12.3% of glycemic prediction variance in machine learning models, highlighting their significance in the inflammatory-metabolic axis.

Psychiatric symptom severity

BPRS scores ranged from 18 to 77, with a mean score of 41.8 (SD = 7.6), placing most participants in the mild-to-moderate severity category. Within this cohort, 44.3% had mild symptoms (BPRS: 32–41), 40% had moderate symptoms (BPRS: 42–53), and 1.4% had severe symptoms (>65).

A statistical analysis revealed that par-

ticipants with BPRS scores >45 were 1.79 times more likely to have hyperglycemia, suggesting a link between psychiatric burden and metabolic dysfunction. Dyslipidemia, particularly hypertriglyceridemia (OR = 2.1, p = 0.036), was also more prevalent in those with severe symptoms. Systemic inflammation appeared to play a crucial role, with leukocytosis observed in 8.5% of high BPRS participants vs. 3.2% in lower-scoring individuals (RR = 2.65, p = 0.017). These findings indicate that psychiatric severity may contribute to metabolic disturbances via inflammatory or endocrine pathways.

A random forest model ranked BPRS scores as the second most influential predictor of hyperglycemia, after CRP levels. A positive correlation between fasting glucose and BMI suggests that metabolic dysregulation may be associated with psychiatric symptom severity (fig. 2). Including BPRS in the model improved prediction accuracy by 9%, reinforcing the role of psychiatric severity in metabolic risk assessment.

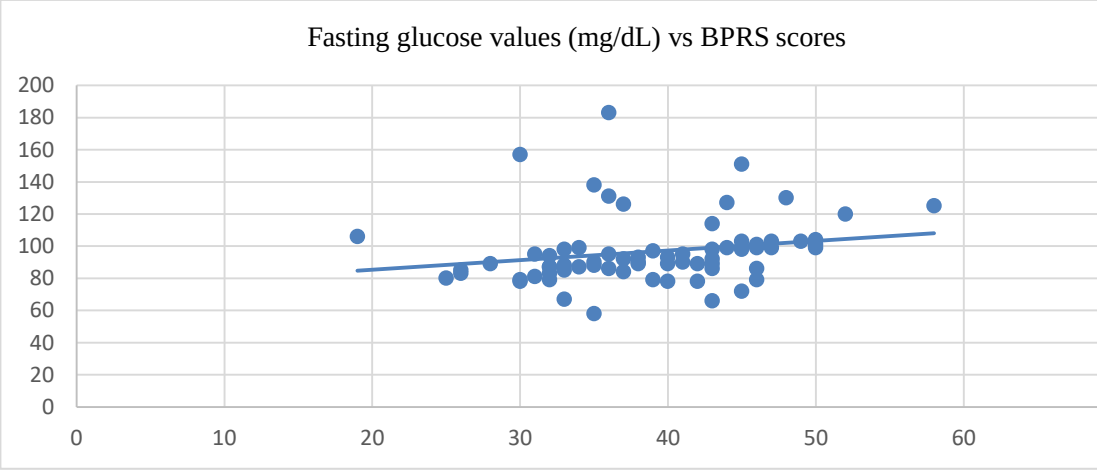

Fig. 2. Correlation graph between Fasting glucose levels (mg/dL) and BMI values

The Positive PANSS scores have a mean of 20.6 with a standard deviation of 6.45, indicating moderate variability in symptoms related to hallucinations, delusions, and other positive schizophrenia symptoms. The Negative PANSS scores average 21.15, with a lower standard deviation (4.29), suggesting more consistency in symptoms such as emotional withdrawal and apathy. The General PANSS scores have a mean of 39.1 with a wider spread (std = 6.65), indicating that general psychopathology symptoms vary more significantly across participants.

In terms of correlations, a moderate positive correlation (0.70) was found between Positive PANSS symptoms and General PANSS scores, suggesting that patients with more severe positive symptoms tend to have higher overall psychopathology severity. Similarly, Negative PANSS symptoms moderately correlated (0.47) with General PANSS, reinforcing the idea that both positive and negative symptoms contribute significantly to the overall illness burden.

Fasting glucose levels (mg/dL) show a positive correlation with both PANSS Gen-

eral and Negative symptom scores (0.54 and 0.39, p< 0.05), suggesting that higher glycemic values may be associated with greater severity of overall psychopathology and specific negative symptoms such as emotional withdrawal and apathy (figs. 3, 4).

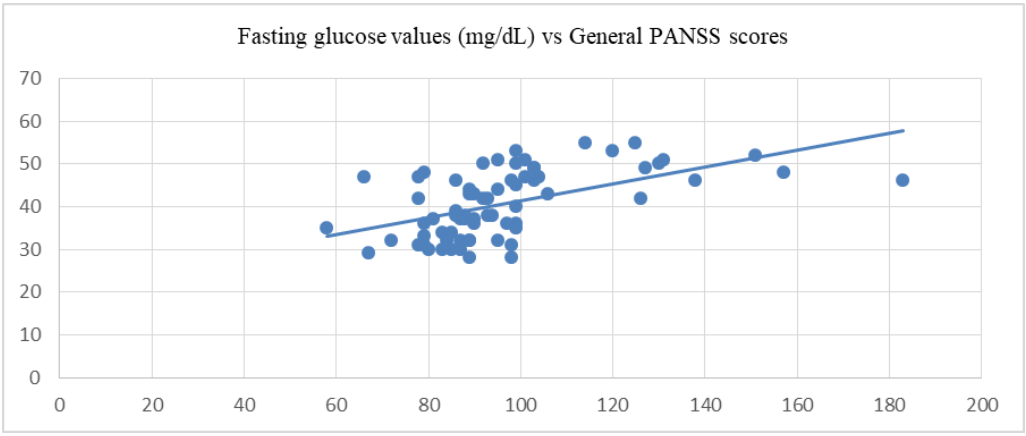

Fig. 3. Correlation graph between Fasting glucose values (mg/dL) and General PANSS scores

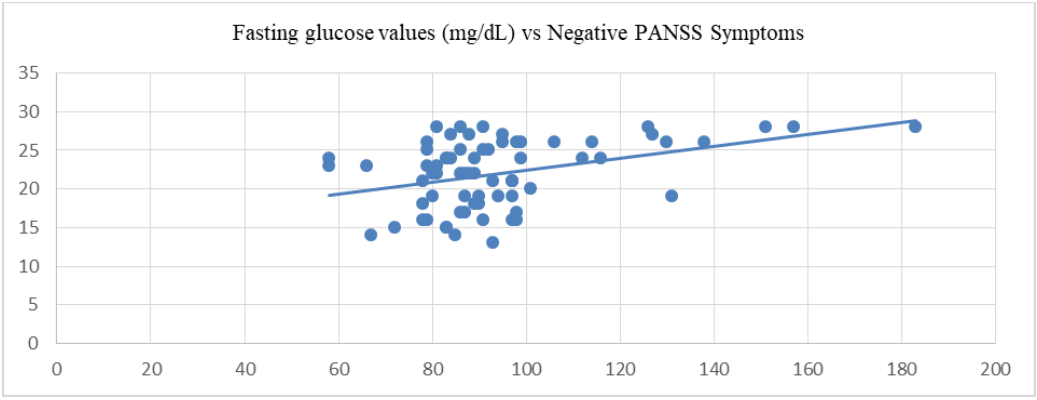

Fig. 4. Correlation graph between Fasting glucose values (mg/dL) and Negative PANSS scores

Body Mass Index (BMI) displayed a positive correlation with Negative PANSS (0.19) and General PANSS (0.29), indicating that higher BMI might be associated with more pronounced negative symptoms such as emotional withdrawal or blunted affect or general symptoms such as unusual thought content, tension or poor impulse control (fig. 5).

Regarding inflammatory markers, CRP (C-reactive protein) showed a significant positive correlation (0.8) with General PANSS, potentially suggesting that higher systemic inflammation may be associated with increased severity of general psychopathological symptoms in schizophrenia or psychotic disorders (fig. 6). Meanwhile, VSH (another inflamma-

tion marker) showed only weak correlations with all PANSS dimensions, suggesting minimal influence on symptom severity.

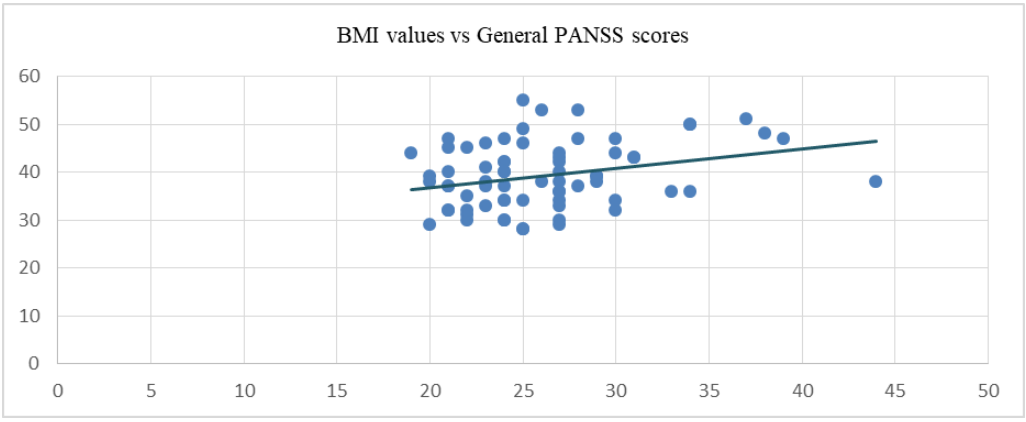

Fig. 5. Correlation graph between BMI values and General PANSS scores.

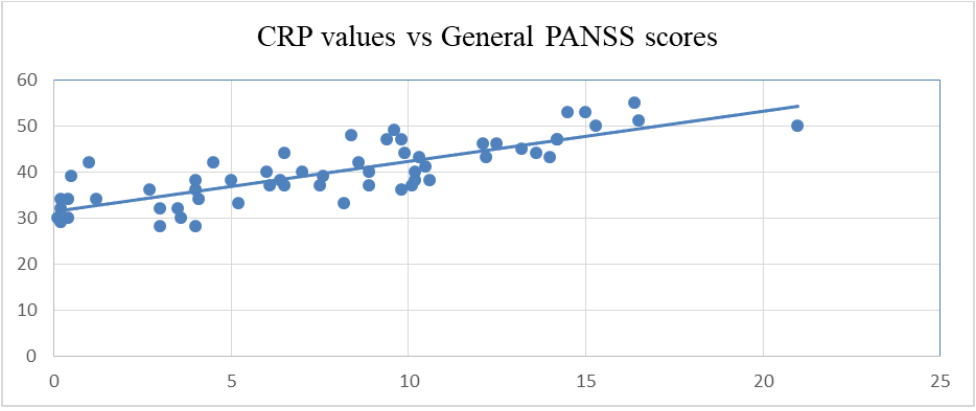

Fig. 6. Correlation graph between CRP values and General PANSS scores

Psychotic symptoms cluster

The psychotic symptom cluster, encompassing delusions, paranoia, and hallucinations, was less frequent but offered unique insights. Delusions, the most prevalent symptom in this cluster, affected 10% of participants. Paranoia and hallucinations were observed in approximately 7% of cases, highlighting their relatively lower incidence within the cohort.

The metabolic impact of psychotic symptoms was subtler compared to behavioral dysregulation. he correlation between delusions and hyperglycemia was weak, suggesting that metabolic dysregulation in this cluster may not be as pronounced. However, psychotic symptoms were significantly associated with inflammatory markers. Participants with delusions were 3.8 times more likely to exhibit elevated CRP levels compared to their non-delusional counterparts. This finding aligns with the broader hypothesis that systemic inflammation, potentially exacerbated by neuro-

chemical imbalances such as dopamine hyperactivity, influence psychotic symptomatology.

Biochemical / hematological markers

Participants with elevated CRP levels (>10 mg/L) and leukocytosis (5.7%) were more likely to exhibit higher schizophrenia severity scores, particularly in the general psychopathology subscale of the Positive and Negative Syndrome Scale (PANSS).

Elevated creatine kinase (CK-NAC), observed in 22.9% of participants, correlated with mild hyperglycemia, suggesting muscle stress or catabolism as potential contributors to glycemic imbalance. Dyslipidemia was common, with 20% and 10% of participants exhibiting hypercholesterolemia and hypertriglyceridemia, respectively. These lipid abnormalities were more frequent among participants with moderate-to-severe schizophrenia symptoms.

Hematological abnormalities, such as neutropenia (11%) and thrombocytopenia (2.9%), were associated with hyperglycemia and higher psychiatric severity scores. Neutropenia, in particular, was correlated with reduced BPRS scores ($\beta=-0.27$, $p=0.042$), likely reflecting the impact of medication-induced immune suppression, particularly from clozapine.

Interactions between symptom clusters and biochemical parameters

Cross-cluster analyses revealed significant interactions. Behavioral symptoms like irritability and agitation exhibited a moderate correlation with flattened affect, suggesting shared neurobiological mechanisms, potentially involving dopamine and serotonin dysregulation. Similarly, agitation showed a modest association with delusions, hinting at overlapping pathways in psychomotor hyperactivity and psychosis.

Machine learning models further enriched these findings. Behavioral symptoms emerged as the strongest predictors of glycemic variability, accounting for 35% of the variance in hyperglycemia prediction. Negative symptoms contributed an additional 18%, while psychotic symptoms added 11%. These models, including Random Forest and Gradient Boosting, achieved robust predictive performance, with R2R^2R2 values exceeding 0.4 and mean absolute errors (MAE) as low as 4.2 mg/dL.

DISCUSSION

This study highlights the strong association between metabolic dysregulation, systemic inflammation, and schizophrenia severity, reinforcing the growing recognition of schizophrenia as a multisystemic disorder. Our findings align with previous research indicating that patients with schizophrenia are at increased risk for diabetes mellitus, independent of antipsychotic medication use (3, 6, 12). The observed prevalence of hyperglycemia (18.6%) and its association with higher BPRS and PANSS scores supports the hypothesis that glycemic abnormalities contribute to worsening psychiatric symptoms (7,9,13). Metabolic disturbances, particularly insulin resistance and chronic hyperglycemia, have been shown to impair cognitive function and exacerbate oxidative stress, both of which contribute to schizophrenia's neuroprogressive course (14, 15, 16). Our results reinforce this link, demonstrating that individuals with higher BPRS scores were nearly twice as likely to exhibit hyperglycemia, while those with elevated inflammatory markers (CRP, ESR) displayed greater psychiatric symptom severity. These find-

ings suggest that metabolic and inflammatory pathways play a crucial role in schizophrenia symptomatology.

The integration of machine learning models provided additional insights into the metabolic-psychiatric connection. BPRS scores and CRP levels emerged as key predictors of hyperglycemia, highlighting the relevance of psychiatric severity and inflammation in metabolic risk assessment. The random forest model improved prediction accuracy by 9% when psychiatric variables were included, reinforcing the role of psychiatric burden in metabolic dysfunction. These findings align with emerging studies demonstrating that AI-driven models can effectively identify schizophrenia subtypes and predict treatment response based on biochemical markers (17, 18, 19, 20).

One of the most striking findings was the strong association between behavioral dysregulation (irritability, agitation) and metabolic abnormalities. Participants exhibiting irritability had a 4.72-fold increased risk of hyperglycemia, suggesting that emotional distress may exacerbate metabolic disturbances via neuroinflammatory mechanisms. Elevated CRP levels in these individuals further support the role of systemic inflammation in linking psychiatric and metabolic dysfunction. These results emphasize the need for integrated screening of metabolic health in patients with severe behavioral symptoms.

Evidence suggests that glucose metabolism alterations are not merely side effects of antipsychotic medication but may be intrinsic to schizophrenia pathophysiology (3). Lee *et al.* (2023) identified impaired glucose metabolism as a potential biomarker for psychiatric disorders, with machine learning models achieving high predictive accuracy in stratifying patient risk (21). Similarly, Zaki *et al.* (2022) developed diagnostic models using peripheral blood markers, reinforcing the role of metabolic parameters in schizophrenia symptoma tology (22).

Our findings support a multidisciplinary approach to schizophrenia management, incorporating metabolic and inflammatory assessments alongside psychiatric evaluations. Routine screening of fasting glucose, lipid profiles, and inflammatory markers may help identify high-risk patients and enable early interventions. Future research should explore longitudinal models to assess whether improving metabolic health leads to reductions in psychiatric symptom severity.

This study has several limitations. The cross-sectional design prevents causal conclusions regarding the relationship between glycemic dysregulation and psychiatric severity. The sample size (N=70) is relatively small, limiting generalizability. Additionally, while machine learning models demonstrated moderate predictive performance ($R^2 > 0.4$), further optimization and validation are needed before clinical application. Future studies should incorporate neuroimaging and multi-omics approaches to improve model accuracy and enhance precision psychiatry strategies.

CONCLUSIONS

This study reinforces schizophrenia as a multisystemic disorder, highlighting the link between metabolic dysregulation, systemic inflammation, and psychiatric severity. Glycemic abnormalities and inflammatory markers correlated with higher PANSS and BPRS scores, suggesting a metabolic-neuroimmune axis in symptom progression. Machine learning models identified glyce-

mic status and inflammation as key predictors, with behavioral dysregulation (irritability, agitation) strongly linked to hyperglycemia.

These findings support integrating metabolic screening into schizophrenia management, as targeted metabolic interventions may improve psychiatric outcomes. Despite limitations, future research should adopt longitudinal and multi-omics approaches to refine predictive models. Leveraging AI-driven biomarker discovery can advance precision psychiatry, leading to personalized, data-driven interventions for schizophrenia patients.

IS OPEN SURGICAL REVASCULARIZATION STILL AN OPTION FOR TREATING CHRONIC MESENTERIC ISCHEMIA? (Abstract): Chronic mesenteric ischemia (CMI) is a condition caused by inadequate blood supply to the gastrointestinal tract for at least 3 months due to atherosclerosis. **Materials and methods:** Diagnosis is often delayed until the patient is referred to a vascular surgery unit. In patients requiring revascularization for CMI, the superior mesenteric artery (SMA) is the primary target vessel using either open or endovascular (EV) techniques. While EV therapy has become the first-line treatment, open surgical re-vascularization remains relevant for selected cases. The revascularization procedure consists of aortomesenteric bypass reconstructing the visceral arteries. **Results:** This paper presents six consecutive cases of CMI treated at the Vascular Surgery Unit of the "Sf. Spiridon" County Clinical Emergency Hospital, Iasi, Romania, between 2014 and 2024. All patients had symptoms suggestive of mesenteric disease, two cases were associated with aorto-iliac disease, one case had *thromboangiitis obliterans*. CT angiography revealed stenotic or occlusive lesions in the celiac trunk and mesenteric arteries in five cases and a fusiform partial thrombosed aneurysm of the SMA in one case. Surgically revascularized mesenteric arteries were SMA and IMA in one case and SMA in four cases. Venous grafts were used for revascularization in three cases and synthetic grafts in two cases. EV treatment consisted of double stenting of the SMA in one case. Primary patency in the surgical group was 60%, and secondary patency was 100%. Symptomatic resolution was observed in all cases. **Conclusions:** Open surgical revascularization remains an important option, especially for patients with extensive mesenteric artery disease. **Keywords:** CHRONIC MESENTERIC ISCHEMIA, MESENTERIC BYPASS.

INTRODUCTION

Chronic mesenteric ischemia (CMI) is defined as ischemic symptoms caused by inadequate blood supply to the gastrointestinal tract, lasting at least 3 months. It is a progressive disease that, if left untreated, can lead to severe complications and death from either starvation or entero-mesenteric infarction (1). With increasing rates of atherosclerotic disease and obesity worldwide, the prevalence of CMI has progressively increased.

The diagnosis of CMI remains challenging due to its non-specific symptoms and the need for advanced imaging techniques. The typical presentation includes postprandial pain, weight loss due to fear of eating, unexplained diarrhea or constipation (2). Diagnosis is often delayed until the patient is referred to a vascular surgeon. The incidence of CMI is less than 1 per 100,000 hospital admissions (3).

CMI is primarily caused by atherosclerosis leading to progressive stenosis of the mesenteric arteries, including the celiac artery (CA), superior mesenteric artery (SMA), and inferior mesenteric artery (IMA).

Typically, significant occlusion of 2 or 3 visceral vessels is required for the patient to become symptomatic. Isolated occlusion of the celiac trunk or superior mesenteric artery alone can lead to symptoms if the collateral network is inefficient (3).

Diagnostic imaging plays a critical role in the confirmation of CMI. In patients with suspected CMI, duplex ultrasound (DUS) of the mesenteric arteries is recommended as a first-line test (2). DUS is also useful for intraoperative assessment of open surgical procedures on the mesenteric arteries. In patients with moderate to high suspicion of CMI, computed tomography angiography (CTA) is recommended to map the occlusive disease and to detect or exclude other intra-abdominal pathology. With 3D reformatting, it can provide excellent reconstructions of the mesenteric arteries (2).

Revascularization is indicated in patients who develop symptoms of CMI. The goals of mesenteric revascularization include relief of symptoms, improvement of quality of life, restoration of normal weight, and improvement of survival by preventing bowel infarction. Once the diagnosis of symptomatic CMI is made, revascularization within a short delay is mandatory to avoid acute exacerbation and bowel infarction by "acute-on-chronic" ischemia (7, 8, 9). Revascularization is the mainstay of treatment, after which the patient can resume oral nutrition.

In patients requiring revascularization for CMI, the SMA is the main target vessel, using either open or EV techniques (4, 5, 6). Characteristics of the SMA that influence treatment selection include vessel diameter, degree of stenosis or occlusion, presence of tandem lesions, degree of calcification, and the extent of collateralization. Open surgical techniques include antegrade bypass (the distal thoracic or supracolic aorta is selected as the inflow source), retrograde bypass (the infrarenal aorta, a previous aortic graft, or the iliac arteries are selected as the inflow source), retrograde open mesenteric stenting (hybrid approach via midline laparotomy to expose the SMA or CA combined with EV retrograde stenting), and endarterectomy (trans-aortic or direct mesenteric endarterectomy) (2).

MATERIALS AND METHODS

This retrospective study presents six consecutive cases of CMI treated at the Vascular Surgery Department of "Sf. Spiridon" County Clinical Emergency Hospital, Iasi, Romania, during 2014-2024. Five patients were male and one patient was female, the mean age was 54.33 years. Two cases were associated with aorto-iliac disease, one case had thromboangiitis obliterans and one case had partial thrombosed aneurysm of SMA with "acute-on-chronic" mesenteric ischemia. All patients presented with postprandial abdominal pain, four patients had significant weight loss, two patients had intermittent claudication and

decreased walking distance (< 50 m). Laboratory tests revealed hypoproteinemia and hypoalbuminemia in four cases. Patients' characteristics are showed in tab. I and the symptoms and anatomical characteristics are resumed in second table.

TABLE I
Patients' characteristics

Patient	1	2	3	4	5	6
Gender	M	M	W	M	M	M
Age	51	60	73	54	45	43
Smoking	Yes	Yes	No	Yes	Yes	Yes
Diabetes Mellitus	No	No	Yes	No	No	No
Dyslipidemia	No	Yes	Yes	Yes	No	No
Hypoproteinemia	Yes	Yes	Yes	Yes	No	No

TABLE II.
Patients' symptoms and anatomical characteristics

Patient	1	2	3	4	5	6
Weight loss	Yes	Yes	Yes	Yes	No	No
Post-prandial pain	Yes	Yes	Yes	Yes	Yes	Yes
Arterial disease	PAD, CVD	PAD	COD	PAD	TAO, COD	Aneurysm SMA
Mesenteric arteries	CA thrombosis at the origin, SMA occlusion	CA thrombosis at the origin, SMA stenosis at the origin	SMA atheromatosis, undetectable flow on the first 3 cm	SMA atheromatosis, critical stenosis on the first 25 mm	SMA stenosis 85-90% at 20mm from the origin	Fusiform aneurysm of the SMA, partially thrombosed, located at 40 mm from the origin

CA-celiac artery, COD- coronary obstructive disease, CVD- cerebrovascular disease,
PAD -peripheral arterial disease, SMA- superior mesenteric artery, TAO-thromboangiitis obliterans

Preoperatively, CT angiography revealed severe CA and SMA stenosis in two cases (cases 1 and 2) with atheromatosis of the abdominal aorta, iliac arteries, and abdominal aortic branches. In three cases (case 3, 4, 5) CTA showed severe SMA atheromatosis at 20 mm from the origin, with flow at the level of the peripheral branches. In one patient (case 6), CT angiography showed a partially thrombosed aneurysm of the SMA located at a distance of 40 mm from the origin, with a maximum diameter of 32 mm and a length of 48 mm.

The surgical procedure for the two cases with aorto-iliac disease consisted of aorto-bifemoral bypass with Dacron graft associated with aorto-SMA and aorto-IMA bypass with autologous graft (GSV) in the first case (fig. 1), aorto-bifemoral bypass with Dacron graft associated with aorto-SMA bypass with venous graft (GSV) in the second case (fig. 2).

TABLE III
Details of surgical procedures

Patient	1	2	3	4	5	6
Procedure	Ao2F bypass (synthetic graft), Aorto-IMA and Aorto-SMA retrograde bypass (venous graft)	Ao2F bypass (synthetic graft), Aorto-SMA retrograde bypass (venous graft)	1. Aorto-SMA bypass; 2. Aorto-SMA bypass (reinforced PTFE graft)	Aorto-SMA bypass (reinforced PTFE graft and distal Miller cuff)	EV treatment double stenting of the SMA (BMS 6x40 mm and 7x60mm)	1. Aorto-SMA bypass (reinforced PTFE graft and Miller cuff), partial aneurysmectomy, SMA ligation distal to the aneurysm; 2. Aorto-SMA bypass (venous graft), right ileum resection, jejune-transverse anastomosis

EV - endovascular, IMA-inferior mesenteric artery,
PTFE-polytetrafluoroethylene, SMA- superior mesenteric artery

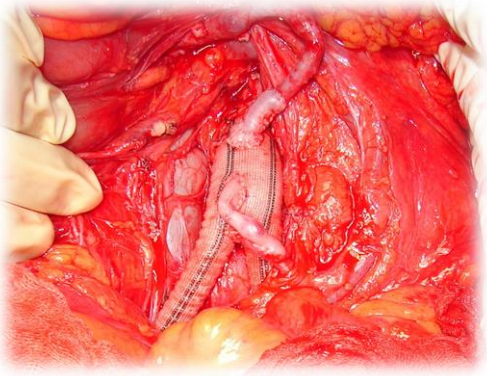

Fig. 1. Aorto-SMA bypass and aorto-IMA bypass- case 1

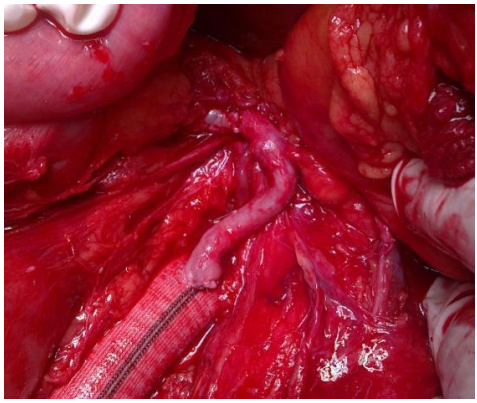

Fig. 2. Aorto-SMA bypass - case 2

The omentum was brought into the aorto-mesenteric space by coloepiploic dissection. In this way, the omentum was used as an anchoring fringe.

The case with a critical stenosis in the first 25 mm of the SMA (case 4) benefited from an aorto-SMA retrograde bypass with a synthetic graft (reinforced PTFE) and a distal Miller cuff (GSV) (fig. 3).

Postoperative CT angiography at 1 month revealed graft patency in these cases.

One of the patients (case 3) was treated surgically in two sequences: aorto-SMA retrograde bypass with venous graft (GSV) followed by aorto-SMA retrograde bypass with synthetic graft (reinforced PTFE) due to venous graft thrombosis. In this case, long-term patency could not be assessed, and the patient was lost to follow-up.

The young patient with thromboangiitis obliterans and critical stenosis of the SMA at 20 mm from the origin (case 5) benefited from EV treatment - balloon angioplasty and double SMA stenting (BMS 6x40 mm

and 7x60 mm) (fig.4).

Fig. 3. Aorto-SMA retrograde bypass with PTFE graft and distal Miller cuff-case 4

Fig. 4. Angiography after stenting-case 5

The case with a fusiform aneurysm of the SMA (case 6) underwent surgery, performing aorto- SMA bypass with reinforced PTFE graft and Miller cuff (GSV), partial aneurysmectomy, SMA ligation distal to the aneurysm. After 24 hours, CT angiography showed graft thrombosis, which required re-intervention with aorto-mesenteric bypass with venous graft, right ileum resection, jejune-transverse anastomosis. CT angio-graphy at 2 and 10 months after revascularization showed graft patency.

After surgery, the patients received the *Triple "A"* therapy (*antibiotic, anticoagulant, analgesic*), combined with vasodilator and hypolipemic agents.

The purpose of this study was to analyze the perioperative outcomes and follow-up results of patients with CMI who were managed in our center.

RESULTS

The five cases treated surgically benefited from CT angiographic control along with DUS follow-up at 1, 2, 3, 6, 12 months and then annually, which showed the patency of the bypass. The case treated EV was followed up with post-procedure control angiography along with periodic DUS at 1, 3, 6, 12 months.

TABLE IV.

Patients' outcomes and complications

Patient	1	2	3	4	5	6
Re-exploration	No	No	Yes	No	No	Yes
Resolution of symptoms	Yes	Yes	Yes	Yes	Yes	Yes
Body weight recovery	Yes	Yes	Yes	Yes	No	No
Imaging follow-up (years)	10	10	2	5	1	1
Imaging modality	DUS/CTA	DUS/CTA	DUS	DUS/CTA	DUS	CTA

Immediate and long-term results were favorable: resumption of physiological intestinal transit (in all cases) and presence of pulse in the peripheral arteries of the

lower limb (in the two cases with aortic and mesenteric revascularization). Remission of symptoms was achieved in 100% of cases. Primary patency in the surgical group was 60% and secondary patency was 100%. Primary patency at 1 year in the endovascular group was 100%.

Antiplatelet monotherapy was used in five cases and dual antiplatelet therapy in one case. With appropriate surgical or EV procedures, problems were resolved. Patients were reintegrated into their families and communities.

DISCUSSION

In daily practice, the clinical decision making for the optimal mesenteric revascularization procedure, remains challenging. In patients with CMI requiring revascularization, the superior long-term outcomes of open surgery must be weighed against the potential early benefit of EV intervention in terms of peri-procedural mortality and morbidity. Several studies have reported that patients with CMI treated with EV techniques appeared to have a higher incidence of symptom recurrence and have recommended EV treatment as a bridge to open surgical revascularization in nutritionally depleted patients with CMI (5). For surgical candidates, prompt surgical intervention is critical, as untreated symptomatic CMI has a 5-year mortality rate approaching 100% (5). Immediate symptom relief is reported in 90-98% of surgically treated patients and remains excellent at 5 years with 89-92% (8).

Mesenteric bypass offers improved patency with lower re-intervention rates and better freedom from recurrent symptoms. A mortality of <3% has been reported for mesenteric bypass performed in large tertiary care centers, although this may be higher in patients presenting late with established bowel infarction (2).

In low-risk patients aged 50 years or younger, open mesenteric revascularization offers the most durable vascular repair for the patient, with a 10-year primary patency rate of 85% (9). Other indications for open mesenteric revascularization include failed EV attempts, stenotic lesions unsuitable for stenting, such as long (>2 cm) stenoses or occlusions, flush ostial occlusions, small (<4 mm diameter) SMA and severely calcified stenosis incorporated into a porcelain aorta (9), and associated aorto-iliac disease (9, 10, 11).

There is no consensus on the best method of mesenteric surgical reconstruction for the treatment of CMI. A variety of open surgical techniques have been described for mesenteric artery reconstruction. The choice includes the type of incision (trans peritoneal vs retroperitoneal), conduit (vein vs prosthetic), graft configuration (antegrade vs retrograde), source of inflow (aortic vs iliac), and number of vessels to be reconstructed (single vs multiple). The type of open reconstruction is selected based on the anatomy and clinical risk assessment of the patient (4). In patients where bowel integrity may be compromised, the bowel should be examined and resected if necessary (12). This was the case of the patient with SMA aneurysm who underwent reintervention (case 6).

In open revascularization, the literature shows good results with revascularization of the SMA alone, with long-term results similar to those with multi-vessel grafts (11). Multivessel bypass reduces the risk of symptomatic recurrence and provides some protection against bowel infarction in the event of single graft occlusion (4). This was our choice in one of the patients (case

2). Autologous revascularization techniques are the first choice, but a prosthetic conduit can also be used as a single or multi-vessel bypass (8). Reports suggest that retrograde grafts perform as well as antegrade grafts (2). All patients operated on in our clinic benefited from retrograde aorto-mesenteric bypass. Permeability is higher with open surgery than with EV therapy, with an average of 70% for both, similar to that of bypasses for peripheral revascularization (3). Because of better long-term and reintervention-free patency, open revascularization should be considered in patients who are fit for surgery, especially those with long segment mesenteric artery occlusion (13). However, in patients deemed fit for open surgery, open surgery is preferred to EV revascularization in patients with long length SMA occlusive disease, flush occlusion, bulky calcification of origin, or dual SMA and celiac occlusion (14, 15).

The largest retrospective, propensity-matched single-center cohort analyzing long-term survival after intervention for CMI concluded that long-term mortality was independent of treatment modality and was associated with patient comorbidities. Therefore, the choice of treatment should be based on anatomic considerations (16).

In terms of secondary patency at 5 years, the surgical approach retains an advantage over the EV approach, with patency of 96-98% for the surgical approach versus 79-88% for the EV approach (17). In the present study, the clinical outcomes were satisfying and similar to the published experiences, secondary patency in surgical group in our series was 100%.

Monjur reported that open surgical revascularization is highly successful in improving symptoms, but is associated with significant 30-day morbidity (21.1%) and mortality (5.8%) (18). Kruger *et al*. presented 12% perioperative morbidity and 2.5% perioperative mortality. Higher values were observed for simultaneous aortic reconstruction, complete revascularization (three branches) and preoperative renal failure (19). Mesenteric revascularization during other concomitant aortic reconstructions remains controversial, as combined reconstructions have higher morbidity and mortality rates. It is also reasonable to perform repair of a single but severe, mesenteric artery stenosis concomitantly with open aortic reconstruction. In the hands of experienced surgeons familiar with mesenteric revascularization, open repair can be performed with low morbidity and mortality. In specialized centers, surgery remains a viable and sometimes preferred option for durable revascularization. Despite the switch to endovascular mesenteric revascularization in most centers since 2002, open revascularization has still its place in selected cases. Appropriate selection of patients is the best guarantee to treatment success and durability (9).

CONCLUSIONS

Despite the advantages of EV therapy, open surgical revascularization retains an essential role, particularly in patients with extensive mesenteric artery disease, associated aorto-iliac disease or failed EV interventions. Surgical intervention is considered in patients with good clinical status and acceptable surgical risk, considering the lower chance of recurrence (16, 20). Open revascularization procedures achieved good results with low procedural mortality, as reported in the literature for selected patients, confirming the utmost importance of open revascularization in

CMI, even in the endovascular era.

ACKNOWLEDGEMENTS

The current study group points out that SMA should be the main target for surgical revascularization in patients with CMI.

QUALITY OF LIFE AND MUSCULOSKELETAL DISORDERS AMONG MEDICAL STUDENTS (Abstract): **The aim** of the study is to evaluate the presence of musculoskeletal disorders and to assess the quality of life among medical students. **Materials and methods**: A total of 105 medical students participated in the study. Data about their posture, the number of sleep hours, body mass index, physical activity, and strategies used to cope with stress were collected, and to evaluate their quality of life, several psychological instruments were used: Perceived Stress Scale (Cohen, Kamarch, & Mermelstein, 1983), Inventory of College Students' Recent Life Experiences (ICSRLE – Kohn, Lafreniere, & Gurevich, 1990), Stress Vulnerability Questionnaire (Sharon & Werner Hoeger, 2021), and The Brief Symptom Inventory (BSI-Derogatis, 1995). The statistical analyses were performed using IBM Statistical Package for Social Sciences (SPSS) Statistics for Windows, *version 24* (*SPSS* Inc., Chicago, IL, USA). **Results:** More than half of the students (61.0%, N = 64) were found to have a moderate level of stress. Women scored higher on this instrument (Mean = 21.93 ± 7.29) compared to men (Mean = 17.08 ± 7.89). More than half of the students scored average or high on this scale, indicating that they are vulnerable to stress (34.3%, N = 36) or even have a high vulnerability to stress (39.0%, N = 31). The number of hours of sleep correlated negatively with the BSI scale (r = -0.29, p = 0.003). The level of physical activity correlates negatively with the PSS scale (r = -0.27, p = 0.004), meaning that the more sports students do, the lower their stress levels. **Conclusions**: The quality of life of participants changes throughout their student life, and many students find various strategies to cope with stress. The study highlights the role of sleep and exercise for a better quality of life. **Keywords:** QUALITY OF LIFE AND MUSCULOSKELETAL DISORDERS, MEDICAL STUDENTS.

INTRODUCTION

Quality of life (QoL) is increasingly recognized as a critical dimension in medical education and healthcare research. The World Health Organization (WHO) defines QoL as an individual's perception of their position in life, shaped by cultural context, value systems, goals, expectations, and concerns (1). Within health sciences, this has been further refined into the concept of health-related quality of life (HRQoL), encompassing physical, psychological, and social domains. Among medical students, QoL is of particular concern, as the demanding academic environment, long study hours, and constant performance pressure

are well-documented risk factors for diminished well-being. Numerous studies have shown that medical students often report poorer psychological health and social relationships compared to their non-medical peers, with high rates of anxiety, stress, and depression. These issues not only undermine academic performance but also have long-term implications for professional competency and patient care.

Musculoskeletal disorders (MSDs) represent an additional yet frequently overlooked challenge to the well-being of medical students. MSDs include a spectrum of conditions affecting muscles, tendons, ligaments, and joints, commonly manifesting as neck, shoulder, and lower back pain. The etiology of MSDs in students is multifactorial, involving prolonged sedentary study, repetitive postures, lack of physical activity, and high psychological stress, as Ikenna *et al*. showed (2). Recent reports indicate that up to 70–80% of medical students experience some form of MSD during their training. These conditions not only impair physical functioning but also exert a negative influence on psychological health, contributing to fatigue, irritability, and decreased concentration. Chronic MSDs have been linked to reduced QoL scores, further reinforcing the need to consider both physical and psychological domains when assessing student well-being (3, 4).

The relationship between QoL, MSDs, and psychological health is complex and bidirectional. Poor QoL may predispose students to musculoskeletal complaints through increased sedentary behaviors and heightened stress, while MSD-related pain and discomfort can exacerbate psychological distress. Moreover, the interplay between these factors can create a self-perpetuating cycle of reduced physical health, impaired academic performance, and deteriorating mental well-being. Understanding these interconnections is vital for designing effective interventions that enhance resilience and promote sustainable health practices among medical students.

To capture the multidimensional nature of QoL and its association with MSDs, validated psychological and clinical tools are widely used in research and practice. Instruments such as the WHOQOL-BREF, SF-36, and the Beck Depression Inventory (BDI) are frequently employed to evaluate global QoL and mental health outcomes, while musculoskeletal-specific questionnaires like the Cornell Musculoskeletal Discomfort Questionnaire (CMDQ), the Oswestry Disability Index (ODI), and the Neck Disability Index (NDI) provide insights into functional limitations and pain severity. In addition, screening tools for stress, anxiety, and depression, including the DASS-21, the Hospital Anxiety and Depression Scale (HADS), and the General Health Questionnaire (GHQ-12), enable a more comprehensive psychological assessment. The integration of these instruments facilitates the evaluation of both general well-being and condition-specific burdens, providing a holistic perspective on student health.

Given the high prevalence of MSDs and the considerable psychological strain faced by medical students, it is imperative to systematically investigate their combined impact on quality of life. Employing standardized assessment tools enables researchers and educators to quantify these effects and identify high-risk groups, while also guiding the development of targeted interventions. Such insights are particularly relevant, as the future healthcare workforce depends not only on academic training but also on the physical and psychological resilience of its members. Accordingly, the

present study aims to explore the interrelationship between QoL, musculoskeletal disorders, and psychological well-being among medical students, drawing on established measurement tools to generate evidence that may inform both institutional policy and individual coping strategies.

MATERIALS AND METHODS

Participants. The research was conducted between January-May 2025 among medical students from different years of study. The respondents were informed about the purpose of the study and the use of the collected data. They were also informed about the confidentiality of the data and that they could stop at any time. No incentive was given to the participants. The research used an online questionnaire, and if they were agreed with the informed consent, they could continue filling in the items. Inclusion criteria: respondents enrolled in medical studies and questionnaires completed before the deadline. Finally, 105 questionnaires were included in the study.

Instruments and Data collection. The questionnaire was constructed using Google Forms application (Alphabet, Mountain View, CA, USA).

a) The first part of the questionnaire gathered socio-demographic and health-related data (such as age, gender, year of study, Body Mass Index - BMI, changes in body composition over time and factors that contributed to this change, chronic disease diagnosis, changes in posture over time, smoker/non-smoker status, drug use, number of hours of sleep per night, engagement in physical activities, and assessment of physical and mental health level).

b) The second part contains questions related to the quality of academic life, such as: number of hours spent per week on academic work, the level of stress or burnout related to academic life, coping mechanisms to deal with stress, various mental health issues, whether studies interfere with the ability to maintain a healthy diet, and university-level changes that could improve students' physical and mental well-being.

c) The third part assesses stress using a classic instrument – the Perceived Stress Scale - Cohen, Kamarch, & Mermelstein, 1983 (5). The instrument comprises 10 items evaluating feelings and participants' thoughts during the last month, and it was designed to measure the degree to which situations in one's life are appraised as stressful. Responses for each item were indicated using a five-point Likert scale (where 0 = Never and 4 = Very Often). There are two subscales in the PSS-10: perceived helplessness, which measures an individual's feelings of a lack of control over their circumstances or their own emotions or reactions, and lack of self-efficacy, which measures an individual's perceived inability to handle problems.

d) The fourth part of the survey assesses exposure to hassles and their influence on health outcomes by way of the Inventory of College Students' Recent Life Experiences *ICSRLE* - Kohn, Lafreniere, & Gurevich, 1990) (6). This scale is comprised of 49 items. Each item is typically rated on a scale (where 0 = Not at all part of my life and 3 = Very much part of my life), and the responses are summed to generate a total score. There are seven factor loadings from the ICSRLE, which are named developmental challenges, time pressure, academic alienation, romantic problems, assorted annoyances, general social mistreatment, and friendship problems.

e) The fifth section evaluates vulnerability to stress by using the Stress Vulnerability Questionnaire - Sharon & Werner Hoeger, 2021 (7).The scale is comprised of

30 items, and it is based on a four-level scoring system from 'strongly agree (1)' to 'strongly disagree (4).'

f) The final part of the survey includes an instrument which measures current or past levels of symptomatology, intensity of symptoms, and number of reported symptoms, respectively – the Brief Symptom Inventory (BSI). It consists of 53 items covering nine symptom dimensions: Somatization, Obsession-Compulsion, Interpersonal Sensitivity, Depression, Anxiety, Hostility, Phobic Anxiety, Paranoid Ideation, and Psychoticism; and three global indices of distress: Global Severity Index, Positive Symptom Distress Index, and Positive Symptom Total - Derogatis, 1995 (8).

Statistical analysis. All analyses for this research were performed by using IBM Statistical Package for Social Sciences (SPSS) Statistics for Windows, version 24 (SPSS Inc., Chicago, IL, USA). Results for descriptive statistics were expressed as means and standard deviations (SD). The normality of data distribution was tested by using the Kolmogorov-Smirnoff test. Given the fact that the data were not normally distributed, bivariate analyses were performed, and non-parametric tests were applied.

To assess comparative results considering gender and diagnosis of a chronic disease, the Mann–Whitney test was performed. Comparative results considering level of physical activity, number of hours of sleep, degree of physical health assumed by the students, degree of mental health assumed by the students, and experiencing burnout due to academic pressure were assessed using the Kruskal–Wallis H test to determine if there are statistically significant differences between more than two groups of an independent variable on a continuous or ordinal dependent variable.

The Spearman correlation was used to test the relationship between variables. A p-value < 0.05 was considered statistically significant.

RESULTS

Socio-demographic and health related data. The participants were aged M = 23.19 ± 14.15 years (with ages ranging between 18 and 37 years old). More than half of the respondents were female (55.2%, N = 58), and more than half are in their 1st (33.3%, N = 35) and 2nd year of study (25.7%, N = 27), respectively.

TABLE I.
Data About Body Composition and Posture

Items	N / %
Changes in body composition	
Increased muscle mass, decreased fat	24 (22.9%)
Increased fat, decreased muscle mass	17 (16.2%)
Lost weight (both fat and muscle)	23 (21.9%)
Gained weight (both fat and muscle)	17 (16.2%)
No significant change	21 (20.0%)
Factors contributed to changes in body composition	
Lifestyle changes (e.g., work, stress, sleep)	36 (34.2%)
Changes in diet, Changes in exercise routine, Lifestyle changes (e.g., work, stress, sleep)	27 (25.7%)
Changes in diet, Changes in exercise routine	7 (6.6%)
Changes in diet, Lifestyle changes (e.g., work, stress, sleep)	7 (6.6%)
Changes in posture over time	
Improved	26 (24.8%)
Worsened	53 (50.5%)
No change	7 (6.6%)

*Frequency and percentages (%)

Results showed that only a third of the participants were of normal weight (30.5%, N = 32), and more than half were underweight (66.7%, N = 70). These changes in body composition experienced by students over the past few years, the main factors that contributed to this change and changes in posture are diverse and are mentioned in first table.

Most participants were non-smokers (74.3%, N = 78) and very few had used illicit drugs (9.5%, N = 10). Approximately one third of the participants engaged in physical activity rarely (35.2%, N = 37), 1-2 times a week (26,7%, N = 28), or 3-4 times a week (26.7%, N = 28). More than half of the participants slept an average of 6-7 hours per night (58.1%, N = 61).

Very few participants suffered from chronic diseases (9.5%, N = 10). Regarding assessment of physical and mental health level, less than half of the participants considered themselves to be in good health, both physically (43.8%, N = 46) and mentally (40.0%, N = 42).

Quality of the academic life

Approximately one third of students spent an average of 10 to 20 hours per week studying (28.6%, N = 30), while the fewest devoted around 40-50 hours (6.7%, N = 7), or even more than 50 hours per week (3.8%, N = 4) to academic work.

More than half of students clearly stated that studies interfere with their ability to maintain a healthy diet (34.3%, N = 36), or only to some extent (36.2%, N = 38).

TABLE II.

Data about Coping Mechanisms and Strategies to Improve Well-Being[1]

Items	N / %
What coping mechanisms do you use to handle stress?	
Hobby (coloring, cooking, listening to music, dancing/partying, reading, walking, traveling, gaming)	26 (24.8%)
Self-encouragement with or without breathing exercises	13 (12.3%)
None/ They don't know how to deal with stress	12 (11.4%)
Sleep	11 (10.4%)
Sport	11 (10.4%)
Meditation/Religion	10 (9.5%)
Talking to someone	8 (7.6%)
Compulsive eating	7 (6.6%)
Smoking	4 (3.8%)
Compulsive TV watching	3 (2.8%)
What changes do you think could improve a students' mental and physical well-being?	
No answer	54 (51.4%)
Having a good community/entourage	8 (7.6%)
More relaxed university schedule	8 (7.6%)
To work mentally with oneself/ To be more relaxed	7 (6.6%)
Extracurricular activities offered by the university	6 (5.7%)
Mental health support/education offered by the university	5 (4.7%)
More support from teachers and the university	5 (4.7%)

[1]Frequency and percentages (%)

Most students experienced study-related stress occasionally (35.2%, N = 37), or frequently (31.4%, N = 33), and more than half experienced burnout due to academic pressure (61.9%, N = 65). However, more than half stated that they do not have access to mental health support (52.4%, N = 55).

When asked *how comfortable they feel when discussing their mental health issues with teachers or colleagues*, on a scale from 1 (very uncomfortable) to 5 (very comfortable), more than a third of students ticked level 3 (31.4%, N = 33).

Coping mechanisms to deal with stress and some of the changes mentioned by students that they believe could improve their physical and mental well-being (tab. II).

Perceived Stress Scale (PSS)

The scale had good internal consistency, as determined by a Cronbach's alpha of 0.86.

The total score for the PSS scale was M = 19.76 ± 7.90, with scores ranging from 0 (0.1%, N = 1) to 37 (0.1%, N = 1). More than half of the students (61.0%, N = 64) were found to have a moderate level of stress. Women scored higher on this instrument (M = 21.93 ± 7.29) compared to men (M = 17.08 ± 7.89).

For PSS subscales, we obtained the following results:

- Perceived helplessness - M = 12.77 ± 7.01,
- Lack of self-efficacy - M = 6.99 ± 3.16.

Inventory of College Students' Recent Life Experiences (ICSRLE)

The Cronbach's alpha score was 0.95 for the total scale. The analysis of Cronbach's alpha revealed the following coefficients: 0.82 for Factor 1 – Developmental Challenge, 0.81 for Factor 2 – Time Pressure, 0.72 for Factor 3 – Academic Alienation, 0.83 for Factor 4 – Romantic Problems, 0.69 for Factor 5 – Assorted Annoyances, 0.82 for Factor 6 – General Social Mistreatment, and 0.83 for Factor 7 – Friendship Problems.

For these ICSRLE subscales, we obtained the following results:

- *Developmental Challenge* - M = 12.40 ± 6.37,
- *Time Pressure* - M = 9.60 ± 4.88,
- *Academic Alienation* - M = 3.61 ± 2.41,
- *Romantic Problems – M* = 2.77 ± 2.72
- *Assorted Annoyances – M* = 3.56 ± 3.02
- *General Social Mistreatment – M* = 5.58 ± 4.25
- *Friendship Problems – M* = 2.97 ± 2.66

The total ICSRLE score was on average M = 50.49 ± 26.45, with scores ranging from 4 (1.0%, N = 1) to 129 (1.0%, N = 1).

Stress Vulnerability Questionnaire (SVQ)

The total score for the SVQ scale was M = 58.16 ± 13.34. More than half of the students scored average or high on this scale, indicating that they were vulnerable to stress (34.3%, N = 36) or even had a high vulnerability to stress (39.0%, N = 31).

The scale had good internal consistency, as determined by a Cronbach's alpha of 0.87.

Brief Symptom Inventory (BSI)

The scale had good internal consistency, as determined by a Cronbach's alpha of 0.98.

The total score for the BSI scale was M

= 63.66 ± 45.35, with scores ranging from 0 (1.9%, N = 2) to 188 (1.0%, N = 1). For the BSI subscales, we obtained the following results:

TABLE III.
BSI Subscales[1]

Subscales	M±SD	Gender differences M±SD		α-Cronbach
		Men	Women	
Somatization	1.10 ± 0.96	0.81 ± 0.90	1.34 ± 0.96	0.88
Obsession-Compulsion	1.51 ± 1.01	1.27 ± 1.02	1.71 ± 0.97	0.89
Interpersonal sensivity	1.26 ± 1.10	1.02 ± 1.01	1.46 ± 1.15	0.84
Depression	1.20 ± 0.96	1.05 ± 0.91	1.33 ± 0.99	0.86
Anxiety	1.30 ± 1.00	1.04 ± 0.98	1.52 ± 0.98	0.87
Hostility	1.13 ± 0.89	1.01 ± 0.95	1.22 ± 0.83	0.78
Phobic anxiety	0.95 ± 1.03	0.83 ± 0.97	1.04 ± 1.08	0.88
Paranoid ideation	1.26 ± 0.94	1.18 ± 0.96	1.29 ± 0.93	0.79
Psychoticism	1.13 ± 0.91	1.00 ± 0.82	1.25 ± 0.98	0.78

[1]Means and standard deviations (M±SD)

Results for the Global Severity Index (GSI), a global index of the BSI , which is the most sensitive indicator of the respondent's distress level and combines information about the number of symptoms and the intensity of distress, are: M = 15.39 ± 11.12, with scores ranging from 0 (1.9%, N = 2) to 44.5 (1%, N = 1).

Comparative and correlational analysis

Results of Mann-Whitney tests showed that there were significant differences depending on gender in PSS scale (z = -3.314, p = 0.001, U = 849.50), ICSRLE scale (z = -2.627, p = 0.009, U = 955.50), and BSI scale (z = -2.237, p = 0.025, U = 997.00). This means that women (Mdn1 = 21.50) are more stressed than men (Mdn2 = 18.00), women (Mdn1 = 55.00) are more affected by minor stressful events than men (Mdn2 = 43.00), and women showed more psychopathological symptoms (Mdn1 = 67.00) than men (Mdn2 = 46.00).

There are significant differences depending on gender in BSI subscales. The results showed that women (Mdn 1 = 1.14) somatized more than men (Mdn2 = 0.57) (z = -3.181, p = 0.001, U = 853.50) and had a higher level of anxiety (Mdn1 = 1.33) compared to men (Mdn2 = 1.00) (z = -2.446, p = 0.014, U = 947.50).

On the Obsession-Compulsion (z = -2.162, p = 0.031, U = 990.00) and Interpersonal Sensitivity subscale (z = -2.039, p = 0.041, U = 1010.00), the results showed that men (Mdn2 = 1.16, Mdn2 = 1.00, respectively) had lower scores than women (Mdn1 = 1.66, Mdn1 = 1.25, respectively).

Significant differences were recorded in terms of diagnosis of a chronic disease (z = -2.323, p = 0.020, U = 262.50), in the sense that students with a positive diagnosis of chronic illness had a higher level of stress (Mdn1 = 28.00), as assessed by the PSS scale, compared to those who were not chronically ill (Mdn2 = 20.00).

Also, comparative analysis for the

ICSRLE scale (z = -3.374, p = 0.001, U = 166.00) showed that those with a diagnosis of chronic disease were more affected by minor stressful events (Mdn1 = 79.00) than those without a diagnosis of chronic disease (Mdn2 = 47.00). At the same time, students with a positive diagnosis of chronic illness had a higher vulnerability to stress (Mdn1 = 68.50), as assessed by the SVQ scale (z = -2.316, p = 0.021, U = 263.00), compared to those who were not chronically ill (Mdn2 = 57.00). Significant differences in this variable were also identified for the BSI scale (z = -2.305, p = 0.021, U = 261.00), in the sense that those with a diagnosis of chronic disease showed more psychopathological symptoms (Mdn1 = 98.50) than those without a diagnosis of chronic disease (Mdn2 = 53.00).

Results of the Kruskal-Wallis test showed that there were significant differences depending on the level of physical activity in the PSS scale ($\chi^2(4) = 11.098$, p = 0.025), in the sense that students who never (Mdn1 = 34.00) or only rarely (Mdn2 = 21.00) practiced sports had a higher level of stress than those who practiced sports daily (Mdn5 = 18.00) or at least 3-4 times a week (Mdn4 = 19.00).

There were significant differences depending on the number of hours of sleep in the SVQ ($\chi^2(3) = 11.185$, p = 0.011) and BSI ($\chi^2(3) = 11.504$, p = 0.009) scales. The results showed that students who slept 4-5 hours a night were more vulnerable to stress (Mdn 2 = 59.00) than students who slept 8 hours a night or more (Mdn4 = 54.00). Additionally, the results showed that students who slept 4-5 hours a night showed more psychopathological symptoms (Mdn2 = 67.00) than students who slept 8 hours a night or more (Mdn4 = 25.50).

Results of Kruskal-Wallis tests showed that there were significant differences depending on the degree of physical health assumed by students in the PSS scale ($\chi^2(4) = 12.276$, p = 0.015) and the SVQ scale ($\chi^2(4) = 12.620$, p = 0.013). This means that those who considered themselves to be in poor physical health had a higher degree of stress (Mdn1 = 29.00) than those who considered themselves to be in excellent physical health (Mdn5 = 15.00) and those who considered themselves to be in poor physical health had a higher vulnerability to stress (Mdn1 = 75.50) than those who considered themselves to be in excellent physical health (Mdn5 = 44.00).

Also, there were significant differences depending on the degree of mental health assumed by students in the ICSRLE scale ($\chi^2(4) = 17.532$, p = 0.002) and the BSI scale ($\chi^2(4) = 23.301$, p = 0.000). This means that those who considered themselves to be in poor mental health were more affected by minor stressful events (Mdn1 = 73.00) than those who considered themselves to be in excellent mental health (Mdn5 = 29.00), and those who considered themselves to be in poor mental health had more psychopathological symptoms (Mdn1 = 66.00) than those who considered themselves to be in excellent mental health (Mdn5 = 21.50).

Results of Kruskal-Wallis test showed that there were significant differences depending on burnout in the PSS scale ($\chi^2(1) = 20.242$, p = 0.000) in the sense that students who felt burnout due to academic pressure were more stressed (Mdn1 = 22.00) than students who did not feel burnout (Mdn2 = 15.00). Also, there were significant differences depending on burnout in the ICSRLE scale ($\chi^2(1) = 6.724$, p = 0.010) indicating that students who felt burnout were more affected by minor stressful events (Mdn1 =

54.00) than students who did not feel burnout (Mdn2 = 36.00).

The Spearman correlational analysis found a positive significant correlation between the level of physical activity and the degree of physical health assumed by the students ($r = 0.42$, $p < 0.001$), indicating that the more students exercised, the healthier they considered themselves physically. The level of physical activity correlated negatively with the PSS scale ($r = -0.27$, $p = 0.004$), meaning that the more sports students did, the lower their stress levels.

The degree of physical health assumed by the students correlated positively with degree of mental health assumed by the students ($r = 0.52$, $p < 0.001$) in the sense that the healthier students considered themselves physically, the healthier they were mentally. Negative correlations were identified between the degree of physical health considered by students and the instruments used in the research: PSS ($r = -0.31$, $p < 0.001$), ICSRLE ($r = -0.21$, $p = 0.031$), SVQ ($r = -0.32$, $p = 0.001$), BSI ($r = -0.21$, $p = 0.026$), which means that the healthier the students were physically, the less stressed they were, the less affected they were by minor stressful events, the less vulnerable they were to stress and the fewer psychopathological symptoms they had.

Also, negative correlations were identified between the degree of mental health considered by students and the PSS scale ($r = -0.51$, $p < 0.001$), the ICSRLE scale ($r = -0.40$, $p < 0.001$), the SVQ scale ($r = -0.28$, $p = 0.003$), and BSI scale ($r = -0.43$, $p < 0.001$), which means that the healthier the students were mentally, the less stressed they were, the less affected they were by minor stressful events, the less vulnerable they were to stress and the fewer psychopathological symptoms they had.

TABLE IV.

A positive correlation was identified between the number of hours of sleep per night and mental health ($r = 0.29$, $p = 0.002$), meaning that the more students slept, the healthier they considered themselves mentally. The number of hours of sleep correlated negatively with the BSI scale ($r = -0.29$, $p = 0.003$), meaning that the more students slept at night, the fewer psychopathological symptoms they had.

Positive correlations were identified between all scales used in the questionnaire. An example of this would be the positive correlations identified between the PSS scale and the ICSRLE ($r = 0.54$, $p < 0.001$), the SVQ ($r = 0.36$, $p < 0.001$), and the BSI ($r = 0.54$, $p < 0.001$) scales, which meant that the more stressed the students were, the more affected they were by minor stressful events, the more vulnerable they were to stress and the more psychopathological symptoms they had.

Strong significant positive correlations were identified between all instruments` subscales (tab. IV)

DISCUSSION

This study highlights several important determinants of stress and psychological well-being among medical students, with particular emphasis on lifestyle, perceived health, and chronic disease status. When compared to previous research, many of our findings align with international patterns.

Students with a diagnosis of chronic disease were significantly more stressed, more vulnerable to stress, and displayed more psychopathological symptoms compared to peers without chronic illness. These results are consistent with earlier findings that medical students with pre-existing conditions such as hypertension, obesity, or diabetes experience greater academic and psychological burden. (9-11) Our findings reinforce the notion that chronic health conditions compound academic stress, magnifying both perceived helplessness and vulnerability.

A strong association was observed between low levels of physical activity and higher stress scores, while regular sports practice correlated with better perceived physical health and lower stress. This supports previous evidence that exercise serves as a protective factor against psychological distress in medical students. Jose J *et al.* (12) and Taylor *et al.* (13) reported similar reductions in anxiety and burnout among physically active students, while Booth *et al.* (14) emphasized the role of inactivity in chronic stress pathways. Collectively, these findings underscore the importance of structured exercise programs in medical curricula to promote resilience.

Students who reported sleeping only 4–5 hours per night were more vulnerable to stress and exhibited more psychopathological symptoms than those who slept 8 hours or more. These results align with evidence from Parto *et al.* (15), Rocha *et al* (16), and Howie *et al.* (17), who identified sleep deprivation as a key contributor to anxiety, depression, and impaired academic functioning in medical students. Our results confirm sleep duration as a central determinant of both perceived mental health and actual psychological symptoms.

Both perceived physical and perceived mental health were strongly associated with stress vulnerability and psychopathological outcomes. Students rating themselves in poor physical health reported higher stress and stress vulnerability, while those rating their mental health as poor were more af-

fected by minor stressful events and exhibited more symptoms. These findings are consistent with Wang *et al.* (18), who showed that life events predicted depression and anxiety particularly among students with higher psychological vulnerability. Similarly, Franzoi *et al.* (19) and Iorga *et al.* (20) found that poorer self-rated health was strongly associated with psychological distress in university students, supporting the link between subjective health perceptions and mental outcomes. Together, these studies reinforce our results by highlighting that both perceived physical and mental health are central predictors of stress sensitivity and psychopathological symptoms in students

A substantial proportion of students reporting burnout also demonstrated higher stress levels and greater sensitivity to stressful events. This finding mirrors reports from Abdel Aziz *et al.* (21), who found high burnout prevalence among UAE medical students, and Maddalena *et al.* (22), who described worsening QoL during high-stress academic periods. Our results confirm burnout as a central mediator of academic distress, suggesting that interventions must address both workload management and psychological support.

Strengths and Limitations of the study: The cross-sectional design limits causal inference, and reliance on self-reported measures may introduce reporting bias. However, the use of multiple validated instruments across a representative student sample strengthens the reliability and generalizability of our conclusions.

Practical implications: The convergence of our results with international evidence suggests that the challenges faced by our medical students are not isolated, but part of a broader global pattern of academic and health-related stress. Interventions such as integrating physical activity programs, promoting healthy sleep habits, ensuring access to mental health services, and addressing burnout through workload reforms could meaningfully improve a student's well-being.

CONCLUSIONS

This study underscores the multifaceted interaction between lifestyle factors, psychological well-being, and perceived QoL among medical students. Our findings demonstrate that inadequate sleep, low levels of physical activity, and the presence of chronic illness are strongly associated with heightened stress vulnerability and increased psychopathological symptoms. Furthermore, burnout and academic pressure emerged as significant contributors to compromised mental health, reinforcing the need for systemic and institutional interventions.

By highlighting the relationships between perceived physical and mental health, stress, and coping mechanisms, this research affirms the value of integrating comprehensive wellness strategies into medical training. Interventions such as promoting adequate sleep hygiene, integrating regular physical activity, and ensuring access to mental health support are not merely desirable but essential in safeguarding the future healthcare workforce. Given that today's medical students are tomorrow's practitioners, prioritizing their well-being should be recognized as a matter of both academic success and public health responsibility.

CONFLICT OF INTEREST AND FUNDING

The authors have no conflicts of interest to declare and the study received no funding.

ENHANCED ANTI-INFLAMMATORY EFFICACY OF NSAID–ANTIBIOTIC COMBINATIONS IN EXPERIMENTAL SUBACUTE INFLAMMATION (Abstract): Subacute inflammation represents a transitional stage between acute and chronic inflammatory processes, characterized by fibroblast proliferation and granulomatous tissue development. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as diclofenac and ketoprofen are widely used to control these processes. Some antibiotics, including cefuroxime and levofloxacin, have also been reported to exhibit secondary anti-inflammatory or immunomodulatory effects. This study investigated the anti-inflammatory efficacy of these agents, administered individually or in combination, using the cotton pellet-induced granuloma model in rats. **Materials and methods:** Adult Wistar rats were divided into experimental groups receiving intraperitoneal doses of NSAIDs and antibiotics alone or in combination. Granulomatous tissue formation was assessed after subcutaneous implantation of sterile cotton pellets, and the degree of inflammation was evaluated by measuring granuloma development and comparing it across treatment groups. **Results:** Both NSAIDs produced clear reductions in granuloma formation compared with the untreated control group, confirming their significant anti-inflammatory potential. Levofloxacin showed a moderate inhibitory effect, consistent with its reported cytokine-suppressive and immunomodulatory properties, whereas cefuroxime exhibited minimal influence on inflammatory tissue growth. When combined, NSAIDs and antibiotics produced a greater reduction in granuloma formation than either agent alone, with diclofenac-based combinations showing the strongest overall activity. **Conclusions:** The findings indicate that diclofenac and ketoprofen effectively suppress subacute inflammatory responses, and that levofloxacin may contribute complementary immunomodulatory effects. Combined administration enhances the anti-inflammatory outcome, suggesting a potential pharmacological synergy between NSAIDs and certain antibiotics in conditions involving both infection and inflammation. **Keywords**: SUBACUTE INFLAMMATION, DICLOFENAC, KETOPROFEN, LEVOFLOXACIN, CEFUROXIME, GRANULOMA.

INTRODUCTION

Subacute inflammation represents an intermediate phase between acute and chronic inflammatory processes, characterized by persistent cellular infiltration, fibroblast proliferation, and granulomatous tissue

formation (1). Unlike acute inflammation, which manifests rapidly through vascular changes, edema, and exudation, subacute inflammation evolves more slowly and reflects the proliferative phase of tissue repair (2). This stage is critical for understanding the transition from acute exudative responses to chronic tissue remodeling, making it highly relevant in the evaluation of anti-inflammatory and antiproliferative agents (3).

Nonsteroidal anti-inflammatory drugs (NSAIDs) exert their effects primarily through inhibition of cyclooxygenase (COX) enzymes, leading to decreased prostaglandin synthesis (4). During subacute inflammation, characterized by the proliferation of fibroblasts, angiogenesis, and infiltration of mononuclear cells, prostaglandins contribute to the persistence of pain, edema, and tissue swelling (5). By reducing prostaglandin production, NSAIDs diminish vascular permeability, decrease leukocyte migration, and alleviate pain and swelling, thereby promoting the resolution of the inflammatory process (6). Additionally, some NSAIDs may exert secondary effects on inflammatory cytokine release and oxidative stress, further contributing to their anti-inflammatory efficacy during the subacute phase of inflammation (7, 8).

DCF is a potent COX-2 inhibitor, producing strong and sustained anti-inflammatory and analgesic effects (9), while KET demonstrates a more balanced COX-1/COX-2 inhibition, resulting in effective suppression of tissue proliferation and exudate formation, though with slightly lower potency than DCF (10). Prolonged or high-dose use of these NSAIDs can lead to gastrointestinal irritation, ulceration, and bleeding. DCF, in particular, has been associated with an increased risk of cardiovascular events such as myocardial infarction and stroke due to its relative COX-2 selectivity (11, 12). Both drugs may also impair renal function by decreasing renal blood flow and sodium excretion, potentially leading to fluid retention, hypertension, or acute kidney injury (13,14). Therefore, while these drugs are valuable anti-inflammatory agents, they should be used at the lowest effective dose and for the shortest duration necessary, especially in patients with preexisting cardiovascular, renal, or gastrointestinal conditions (15).

Beyond traditional NSAIDs, certain antibiotics, have been reported to influence inflammatory processes indirectly, potentially through modulation of cytokine release, reduction of oxidative stress, or interference with leukocyte activity. Although their primary role remains antimicrobial, these agents may exert adjunctive anti-inflammatory or immunomodulatory actions (16). Cefuroxime (CFX), a second-generation cephalosporin, is a broad-spectrum β-lactam antibiotic effective against both Gram-positive and Gram-negative bacteria, with minimal direct anti-inflammatory activity but potential to indirectly reduce inflammation through infection control (17). Levofloxacin (LFC), a third-generation fluoroquinolone, is a broad-spectrum antimicrobial agent that inhibits bacterial DNA gyrase and topoisomerase IV, exhibiting potent activity against both Gram-positive and Gram-negative organisms and demonstrating additional anti-inflammatory and immunomodulatory effects through suppression of cytokine release and oxidative stress (18, 19).

The present study **aimed** to evaluate the anti-inflammatory efficacy of DCF and KET, administered alone or in combination with CFX or LFC, using the cotton pellet-

induced granuloma model in Wistar rats. The formation and dry weight of granulomatous tissue were used as objective parameters to quantify subacute inflammation. By examining potential pharmacological interactions between NSAIDs and antibiotics, this study sought to elucidate whether such combinations could modify or potentiate the suppression of subacute inflammatory responses, offering insights relevant to both experimental pharmacology and clinical therapeutics.

MATERIALS AND METHODS

Animals. Adult male Wistar albino rats, weighing 200-250 g, were used as the experimental model. The animals were sourced from the National Medical-Military Institute for Research and Development, Băneasa (Bucharest, Romania), and transported under controlled conditions to the Biobase facility of the Grigore T. Popa University of Medicine and Pharmacy Iasi.

Upon arrival, rats underwent a mandatory 14-day quarantine period. They were accommodated in individually ventilated cages within the experimental animal facility of the CEMEX. The environment was maintained at a temperature of 20 ± 4°C, relative humidity of 50±5%, and a 12:12-hour light/dark cycle to simulate natural circadian rhythms. The housing environment was carefully regulated, ensuring stable thermal conditions (approximately 20±4°C), balanced humidity levels (around 50±5%), and a 12:12-hour light/dark cycle to simulate natural circadian rhythms. Throughout the study, the animals had continuous access to drinking water and a nutritionally balanced laboratory diet. Prior to experimental manipulation, animals underwent a 24-hour acclimatization period to reduce stress and allow adaptation to the new environment.

To control for circadian variation in physiological parameters, all experimental procedures were performed within a fixed time frame, between 7:00 a.m. and 19:00 p.m. each day. Throughout the study, rats had unrestricted access to a standardized commercial rodent diet (pelleted form). Individual food intake was monitored daily to ensure nutritional consistency. Fresh drinking water was supplied ad libitum through automated systems designed to maintain cleanliness and prevent spillage.

On the day of the experimental procedures, animals were subjected to a fasting period during which both food and water were withheld to avoid potential interference with biochemical and physiological measurements.

The cotton pellet-induced granuloma model. The experiments were conducted under strictly controlled laboratory conditions at the Prof. Ostin C. Mungiu Advanced Research and Development Center for Experimental Medicine (CEMEX), within the Grigore T. Popa University of Medicine and Pharmacy Iași, Romania. All procedures adhered to standardized environmental parameters and animal care protocols to ensure experimental consistency.

For the experiment, nine groups of five animals each were used, receiving intraperitoneal administrations every 12 hours for three days at the same volume as follows: Group C: saline solution - positive control; Group KET: ketoprofen 15 mg/kg; Group DCF: diclofenac 15 mg/kg; Group CFX: cefuroxime 20 mg/kg; Group LFC: levofloxacin 5 mg/kg; Group KET+CFX: ketoprofen 15 mg/kg + cefuroxime 20 mg/kg; Group KET+LFC: ketoprofen 15 mg/kg + levofloxacin 5 mg/kg; Group DCF+CFX: diclofenac 15 mg/kg + cefuroxime 20 mg/kg; Group DCF+LFC:

diclofenac 15 mg/kg + levofloxacin 5 mg/kg. All injectable solutions were freshly prepared immediately before administration and pre-warmed to 36.7°C. Sterile, single-use syringes were employed for all injections.

Each animal was weighed individually using a high-precision automated balance (Sartorius AG, UK; accuracy ±0.1 g). Dosages were adjusted throughout the study to account for any variations in body weight.

At the beginning of the experiment, rats were anesthetized via inhalatory anesthesia with Isoflurane – Isoflutek, KRKA. Following anesthesia, the dorsal area was shaved, and a small incision was made at each implantation site. Sterile cotton pellets, each weighing 62 mg, were inserted subcutaneously, one the right flank. The implanted pellets acted as foreign bodies, eliciting a localized inflammatory response characteristic of subacute granulomatous inflammation (20). The development of granulomatous tissue was monitored visually throughout the observation period.

On day eight, the animals were weighed again and then anesthetized before being euthanized through isoflurane overdose. The granulomatous tissue encapsulating each cotton pellet was meticulously excised and separated from the surrounding tissue. The wet pellets were first weighed to record their wet weight, then dried in an incubator at 60 °C for 18 hours until a constant (completely dry) weight was reached. After drying, the pellets were weighed again. The amount of exudate (in mg) was determined by subtracting the dry weight from the wet weight. Granulation tissue formation (dry granuloma weight) was calculated by subtracting the weight of the cotton pellet (62 mg) from the constant dry weight.

The inhibition of granuloma weight gain (%) was calculated according to the following formula (21): [(Dry weight of granuloma in treated animals - Dry weight of granuloma in C) / Dry weight of granuloma in C] x 100.

Statistical analysis. Data analysis was performed using SPSS software, version 24 (IBM Corp., Armonk, NY, USA). Group comparisons were primarily conducted using one-way analysis of variance (ANOVA), followed by Tukey's post hoc test for multiple comparisons when significant differences were identified. Results were expressed as mean ± standard deviation (SD), with variance and interquartile range also computed. For comparisons between two independent groups, Student's t-test was applied; when normality or homogeneity of variance assumptions were not met, the nonparametric Kruskal-Wallis test was used instead. Correlation analyses employed Pearson's coefficient for parametric data and Spearman's rank correlation for nonparametric data. Simple and multiple linear regression models were applied to evaluate the influence of one or more independent variables on the dependent variable. Statistical significance was established at $p<0.05$.

Ethical considerations. All experimental activities were performed at CEMEX in full compliance with the ethical principles governing animal experimentation, as outlined in the European Directive 2010/63/EU (22) and the Romanian Law No. 43/2014 regarding the protection of animals used for scientific purposes (23). The study protocol was thoroughly evaluated and authorized by the Ethics Committee of the Grigore T. Popa University of Medicine and Pharmacy of Iasi (Approval No. 553/06.03.2025), as well as by the Romanian National Sanitary Veterinary and Food Safety Authority (Authorization No. 79/15.04.2025).

RESULTS

Body weight variation in experimental animals serves as an indirect but valuable indicator of general health status, metabolic balance, and potential systemic effects of the tested compounds. In subacute inflammation models such as the cotton pellet-induced granuloma test, weight gain over the observation period is expected due to normal growth and recovery processes. Conversely, a reduced increase or weight loss may indicate systemic stress, altered metabolism, or potential drug-induced adverse effects. The C group exhibited a mean body weight increase of +7.5 g after seven days, reflecting normal physiological growth under experimental conditions. Treatment with anti-inflammatory agents led to a noticeable attenuation of weight gain, with the magnitude of this effect varying across groups (tab. I).

Both KET and DCF groups showed a statistically significant reduction in body-weight gain compared to controls, with mean increases of +5.4 g ($p<0.05$) and +3.8 g ($p<0.01$), respectively. This pattern suggests that NSAID administration may slightly suppress appetite and nutrient absorption or influence metabolic rate through prostaglandin inhibition, mechanisms known to contribute to reduced weight gain during prolonged treatment. The more pronounced effect observed in the DCF group aligns with its stronger COX-2 inhibitory potency and systemic anti-prostaglandin action. CFX and LFC, demonstrated modest, nonsignificant or mildly significant decreases in weight gain (+6.7 g, and +5.9 g, respectively), indicating that these agents, when administered alone, exert limited systemic impact on growth and metabolism (tab. I).

When combined with NSAIDs, all dual-treatment groups exhibited a further reduction in weight gain compared with the control. The DCF-based combinations produced the most marked effects (+3.6 g, and +3.3 g, both $p<0.01$), suggesting possible additive systemic influences or metabolic interactions between DCF and the co-administered antibiotics. KET-based combinations also resulted in significant, though slightly less pronounced, reductions (+5.1 g, and +4.9 g, respectively) (tab. I).

TABLE I.

Variation in body weight of rats seven days after pellet implantation

Groups	Mean changes in animal`s body weight 7 days after subcutaneous pellet implantation (g).
C	+7.5±0.3
KET	+5.4±0.01*
DCF	+3.8±0.05**
CFX	+6.7±0.1
LFC	+5.9±0.3*
KET+CFX	+5.1±0.5*
KET+LFC	+4.9±0.3**
DCF+CFX	+3.6±0.05**
DFC+LFC	+3.3±0.03**

Data are expressed as the mean ± SD for five animals per group.
*p<0.05, **p<0.01 compared with the C group.

All the experimental groups showed an increase in granuloma mass after seven days compared to M0, confirming the successful induction of subacute inflammation through cotton pellet implantation. However, the extent of granulomatous tissue formation varied significantly between treatment groups, reflecting the anti-inflammatory effects of the tested substances. The C group exhibited the highest granuloma mass after seven days (112.2±6.33 mg), consistent with the ex-

pected progression of fibroblast proliferation, collagen deposition, and inflammatory cell infiltration in untreated subacute inflammation (fig. 1).

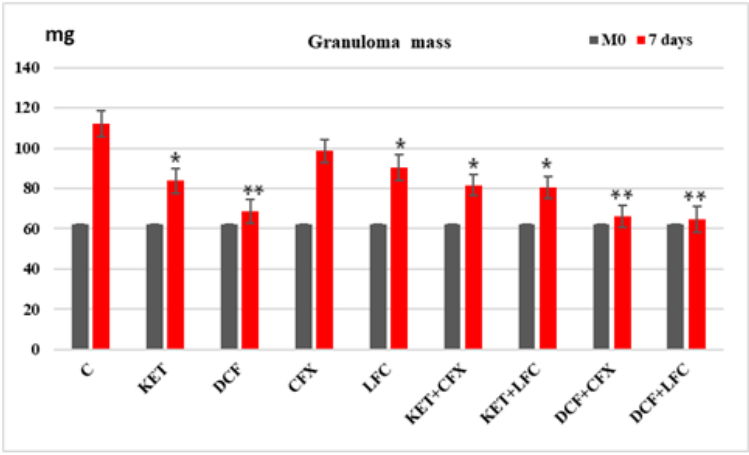

Fig. 1. Changes in granuloma weight 7 days after subcutaneous pellet implantation. Data are expressed as the mean ± SD, based on 5 animals per group. *p<0.05; **p<0.01 *vs.* Control-p group.

Administration of NSAIDs markedly reduced granuloma formation. Both KET and DCF significantly inhibited granulomatous tissue proliferation compared to the control group (p<0.05, and p<0.01, respectively). The stronger inhibitory effect observed with DCF suggests greater suppression of the proliferative phase of inflammation, likely due to its higher COX-2 inhibitory potency and consequent reduction in prostaglandin-mediated fibroblast activation and collagen synthesis. Among antibiotic monotherapies, LFC induced a mild but statistically significant decrease (p<0.05). This finding aligns with reports that fluoroquinolones may exert ancillary anti-inflammatory or immunomodulatory effects through inhibition of pro-inflammatory cytokines and oxidative mediators, while β-lactams such as CFX have minimal impact on inflammatory pathways (fig. 1). Combination treatments generally enhanced the anti-inflammatory outcome compared to individual drug administration. The KET+CFX, KET+LFC, and DCF+CFX groups all exhibited significant granuloma inhibition (p<0.05, or p<0.01), suggesting additive or synergistic effects between NSAIDs and antibiotics. The most pronounced reductions were observed in the DCF+CFX and DCF+LFC groups (p<0.01), indicating that DCF-based combinations were particularly effective in limiting fibroproliferative tissue formation (fig. 1).

The effects of the tested treatments on granuloma formation were evaluated by determining the percentage inhibition of granuloma weight gain in the pellet-induced granuloma model. All treatment groups produced varying degrees of inhibition compared with the control group, DCF produced the highest inhibitory effect among the single-drug treatments, with a mean inhibition of 38.9±2.33%, followed by KET at 25.3±1.82%, LFC at 19.4±2.21%, CFX at 12.1±2.67% (tab. II).

TABLE II.
The inhibition of granuloma weight gain

The inhibition of granuloma weight gain	
Groups	**%**
KET	25.3±1.82*
DCF	38.9±2.33**
CFX	12.1±2.67
LFC	19.4±2.21*
KET+CFX	27.3±1,67*
KET+LFC	28.3±2.37*
DCF+CFX	41.0±1.55**
DCF+LFC	42.5±1.45**

Data are expressed as the mean ± SD for five animals per group.
*p<0.05, **p<0.01 compared with the C group.

Combination therapy generally enhanced the inhibitory response. The combination of DCF with LFC produced the greatest inhibition (42.5± 1.45%), slightly exceeding that of DCF + CFX (41.0±1.55%). The KET-based combinations also showed improved inhibition compared with KET alone, with 27.3± 1.67% for KET+CFX and 28.3±2.37% for KET+LFC (tab. II).

DISCUSSIONS

The cotton pellet-induced granuloma model in rodents is a classical and widely accepted approach for studying the subacute phase of inflammation. When sterile cotton pellets are implanted subcutaneously, they provoke a localized and sustained inflammatory reaction marked by fibroblast proliferation, collagen synthesis, macrophage and lymphocyte infiltration, and the development of new blood vessels. Over time, these cellular and molecular events culminate in the formation of granulomatous tissue around the pellet (20). Measuring the dry weight of this tissue provides a reliable quantitative index of fibroplasia and tissue repair. Consequently, a reduction in granuloma mass reflects the anti-proliferative or anti-inflammatory potential of tested compounds, offering valuable insight into mechanisms involved in the resolution of subacute inflammation (24).

In this study, the control group exhibited the greatest increase in body weight, reflecting normal physiological growth. Treatment with NSAIDs led to a moderate reduction in weight gain, most evident in DCF-treated animals. This effect is likely related to COX inhibition, which can influence gastrointestinal integrity, appetite, and metabolism. Animals receiving antibiotics, alone or in combination with NSAIDs, showed only mild weight suppression, suggesting minor metabolic or gastrointestinal stress without signs of overt toxicity or behavioral disturbance.

Analysis of granuloma mass provided complementary evidence of systemic drug effects. All pharmacological interventions reduced granuloma formation relative to controls, indicating effective modulation of subacute inflammatory responses. Among the NSAIDs, DCF produced the strongest inhibition of granuloma tissue development, followed by KET. The pronounced efficacy of DCF aligns with the suppression of prostaglandin synthesis, fibroblast proliferation, and collagen deposition (25). KET, also significantly reduced granuloma mass, though to a lesser degree. These outcomes support existing evidence that COX inhibition attenuates fibroproliferative inflammation and may modestly influence body-weight dynamics during prolonged inflammatory states.

The antibiotics displayed distinct profiles. LFC significantly decreased granuloma weight, whereas CFX produced only a minor, non-significant effect. The superi-

or activity of LFC may stem from its documented ancillary anti-inflammatory actions, particularly the inhibition of cytokine release (e.g., TNF-α, IL-6, IL-1β) (19) and suppression of NF-κB signaling, resulting in reduced leukocyte infiltration and fibroblast activation (26). Further research has reported that LFC effectively reduces pulmonary inflammation through the suppression of pro-inflammatory cytokines and chemokines, including TNF-α, IL-6, and MCP-1 (19,27,28). It also demonstrates significant anti-inflammatory effects *in vitro* by reducing proinflammatory cytokine secretion in human bronchial epithelial cells culture, indicating potential immunomodulatory benefits in addition to its antibacterial activity in chronic pulmonary infections (28-30). Complementary findings have also indicated that LFC exerts inhibitory activity on the lipoxygenase, which plays a role in lipid peroxidation and oxidative inflammatory pathways (31, 32). Collectively, these studies support the view that LFC exhibits measurable anti-inflammatory actions beyond its antimicrobial role, likely mediated through modulation of cytokine signaling and oxidative stress responses.

CFX, by contrast, exhibits limited interaction with inflammatory mediators and may even trigger mild pro-inflammatory responses under certain conditions. CFX, is primarily recognized for its broad-spectrum antibacterial efficacy, with scarce data indicating anti-inflammatory or immunomodulatory effects on human bronchial epithelial cells (29, 30). Therefore, while LFC appears to exert a modest yet consistent anti-inflammatory effect, CFX shows minimal evidence of such activity when administered alone.

Combination treatments revealed notable interactions. Co-administration of NSAIDs with either antibiotic enhanced the inhibition of granuloma formation, with the DCF-LFC pairing demonstrating the greatest effect. This potentiation likely arises from complementary mechanisms, NSAID-mediated suppression of prostaglandin pathways, alongside antibiotic modulation of cytokine activity and oxidative stress. The DCF combinations consistently outperformed those involving KET, underscoring the stronger anti-proliferative impact of selective COX-2 inhibition. The findings confirm that DCF exerts the most potent anti-inflammatory action in this subacute granuloma model, while LFC contributes additional immunomodulatory benefits, particularly when used in combination. Although CFX shows limited direct anti-inflammatory properties, it may enhance NSAID efficacy through pharmacodynamic interaction. These results highlight the potential therapeutic value of combining NSAIDs with specific antibiotics, especially in clinical contexts characterized by concurrent infection and inflammation. Nevertheless, further investigations are required to elucidate the precise mechanisms underlying these interactions, evaluate long-term safety, and determine whether the observed experimental synergy translates into tangible clinical advantages.

CONCLUSIONS

The present study demonstrated that both DCF and KET exerted significant anti-inflammatory effects in the cotton pellet-induced granuloma model, confirming their efficacy in modulating the proliferative phase of subacute inflammation. Among the antibiotics tested, LFC produced a moderate but statistically significant reduction in granuloma formation,

consistent with its reported immunomodulatory and cytokine-suppressive properties, while CFX showed minimal direct anti-inflammatory activity. Combination therapy enhanced the inhibition of granulomatous tissue formation compared with single-drug treatments, particularly in DCF-based regimens, suggesting additive or possibly synergistic effects between NSAID-mediated prostaglandin suppression and antibiotic-mediated cytokine modulation. These interactions may hold clinical relevance in conditions characterized by coexisting infection and inflammation, where combined anti-infective and anti-inflammatory strategies could improve therapeutic outcomes. Further studies involving larger cohorts, extended treatment durations, and molecular assays are required to confirm the observed pharmacodynamic interactions and to elucidate the mechanisms underlying the immunomodulatory potential of antibiotic-NSAID combinations.

SAFETY OF CONTRAST ADMINISTRATION IN COMPUTED TOMOGRAPHY ANGIOGRAPHY IN PEDIATRIC CONGENITAL HEART DISEASE: A 9-YEAR SINGLE CENTER COHORT OF 697 EXAMS (Abstract): Pediatric cardiovascular congenital disease (CHD) diagnosis benefits greatly from thoracic computed tomography angiography (CTA), with an increasing number of referrals. **The aim** of this study was to evaluate the safety of CTA examinations in pediatric patients with congenital cardiovascular malformations. **Materials and methods**: A 9-year retrospective analysis of pediatric CTA reports was performed. 697 consecutive examinations were included, with recorded data consisting of demographic data of the patient and procedure-related information (cannulation type, site of venous access, type and volume of contrast agents, injection flow rate, dose and adverse events). **Results**: The median patient age was 199 days (interquartile range IQR [15,1714.5]), with a male: female ratio of 1.29. The most frequent peripheral cannulation site was the left antecubital fossa 265 cases (38.02%), and the most frequently used cannula size was 24-gauge (331 cases); a central line was used in 101 cases (14.49%). The flow rates for peripheral and central venous catheters were 0.3 to 5 mL/s, median 1.00, [0.8, 2.0] and 0.5 to 4 mL/s, median 0.9 [0.8, 1.0] respectively. Nine cases of contrast media extravasation (1.29%), four minor allergic reactions (0.6%), two cases of placement of the central venous catheter in the artery (0.29%), one case of air embolus (0.14 %) and one anaphylactic shock (0.14%) were recorded. **Conclusions**: In a single-center cohort of 697 pediatric CTAs for congenital heart disease over 9 years, complication rates related to contrast and venous access were low (extravasation ~1.3%; allergic reactions ~0.6%; anaphylaxis ~0.14%), all resolved favorably. Central line incidents were rare. The results support the safety of contrast administration in pediatric CTA of congenital heart disease, with the recommendation to verify the prescan and standardize protocols**.** **Keywords***:* CONGENITAL HEART DISEASE, CT ANGIOGRAPHY, CONTRAST MEDIA, PEDIATRIC.

INTRODUCTION

CT Angiography (CTA) has become a vital non-invasive diagnostic tool with extremely high clinical value for cardiovascular pathology due to recent advancements in multidetector CT scanner technology that have enabled faster anatomical coverage and high submillimeter spatial resolution for larger body scan volumes(1, 2).

Formerly considered in the context of

pediatric use due to associated exposure to ionizing radiation, CTA has recently become a robust imaging modality, providing excellent input for pre and post-therapeutic management of congenital heart disease (CHD)(3-6).

Including a broad spectrum of indications, in the context of CHD, CTA mainly focuses on the anatomical mapping of normal and variant cardiac chambers and the great vessel arrangements, proximal and distal pulmonary arteries, the imaging of normal and abnormal venous anatomy, the detailed analysis of coronary vessels (especially important for surgical planning to treat Tetralogy of Fallot (TOF)), congenital or acquired arterial stenosis, and assessment of aortopulmonary collateral arteries in patients with pulmonary atresia(4, 7-10).

Pediatric cardiovascular CT imaging is performed after intravenous contrast medium injection, with multiple techniques available for contrast agent administration(11). The main challenge in CTA for pediatric CHD is the use of small-bore angiocatheters, which sometimes must be placed in unusual and minute access sites to deliver small volumes of contrast medium while obtaining the appropriate vascular enhancement(12-14).

Due to the possibility of contrast extravasation, volume, maximum flow rate, contrast type, and osmolarity (15-17), must be considered. Pediatric patients, especially those with preexisting cardiac dysfunction, have lower tolerance to intravascular fluid changes, which can be triggered if a hyperosmotic contrast medium is provided, so non-ionic, low- or iso-osmotic iodinated contrast material is preferred(18-20) even if it could provide less enhancement(21).

For children undergoing CTA, contrast material is delivered by a power injection through small peripheral angiocatheters (22-26 gauge) placed in antecubital veins (preferably the right arm, to avoid hardening artifacts in the innominate vein) or in feet, as well as central venous catheters (jugular or femoral). A high viscosity contrast agent increases the pressure associated with intravascular injection, ultimately limiting the maximum injection rate. This can cause failure to obtain the desired flow rate or even catheter failure and extravasation of contrast material with possible vessel injury. The use of power injectors has become the most common method for delivering contrast media for CTA(12, 22-25).

The aim of this study was to evaluate the safety of CTA exams in pediatric patients with congenital cardiovascular malformations. Our hypothesis was that CTA examinations performed in a pediatric congenital cardiovascular population represent a rather safe procedure, with a rate of incidents similar to that in the general population.

MATERIALS AND METHODS

A retrospective review of data collected from computed tomography angiography examinations reports of a single center- a tertiary cardiovascular teaching hospital was performed, following Ethics Committee retrospective approval (5718/08.07.2024), with exemption from informed consent for the file analysis. For minor patients, consent for the medical procedure/imaging was obtained from the legal guardian, in accordance with institutional policy.

Patient and procedural data were collected from consecutively performed CTA. All patients under 18 years of age underwent computed tomography angiography to evaluate cardiovascular anatomy or function between February 2015 and July 2024.

Examinations were considered and included in the database if they were ordered for a patient with congenital cardiovascular disease to evaluate anatomy or function.

Exclusion criteria included CTA examinations performed for evaluation of non-cardiovascular indication, incomplete demographic or reporting records, and reports mentioning non-diagnostic scans. Acquisition protocols have been developed according to multi-society recommendations, considering the available infrastructure.

Relevant information was collected from radiological records, including patient demographics (age, gender, weight, height, indication), procedure-related data (cannulation type, site of venous access, type and volume of contrast agents used, injection flow rate), and adverse events (erythema, nausea, vomiting, anaphylactic shock) or technical issues (extravasation, line misplacement). Examinations in which any of the above-mentioned data were missing were excluded from the study.

In pediatric cardiac CT imaging using the Mallinckrodt OptiVantage system, it is essential to balance image quality and radiation exposure. For children, 80-100 kVp is typically used to minimize radiation, with mAs adjusted according to the patient's weight: 1-30 mAs for infants and 30-60 mAs for older children. The CARE dose system optimizes the mAs automatically based on body size and anatomical area. Collimation is set tightly around the heart to reduce unnecessary radiation, and the pitch is typically 1.0-1.5, ensuring optimal resolution while maintaining scan speed. ECG gating is used to synchronize the scan with the cardiac cycle, usually capturing the 50%-75% phase to reduce motion artifacts. Contrast is administered at 1.5-2.5 mL/kg of body weight, with concentrations of 300-370 mg/mL, and followed by 0.5-30 mL saline to flush the contrast from the system. The contrast temperature is maintained at 37°C to prevent reactions and ensure smooth injection. These settings are carefully adjusted to provide high-quality cardiac imaging while minimizing risks, such as radiation exposure and contrast-related issues, especially in pediatric patients.

The flow rate used in each case was established according to the local protocol, depending on the cannula size, ranging from 0.3 mL/s in the case of central lines and 26-gauge cannula up to 5 mL/s in case of large-bore 16-gauge cannula.

The amount of contrast medium used varied depending on the patient's weight and body height ranging from 3 to 100 mL. In all cases, a bolus tracking technique was used, with a threshold of 150 Hounsfield units and a region of interest determined by clinical indication.

Until approximately 2019, none of the patients underwent pre-medication for contrast agent reaction prophylaxis. Starting in that year, all patients capable of receiving oral medication were treated with Medrol 32 mg (in general between 0.5-1 mg/kg) 12 hours before examination and Medrol 32mg + Loratadine 5/10 mg one hour before. If the patients were unable to take oral medication, we replaced each corticoid with 4-8 mg/kg of hydrocortisone IV. Premedication was introduced not only for patients with a history of contrast reactions but also to minimize the risk of adverse reactions, even in the absence of prior tests, given the underlying cardiac conditions of the patients. For those already under treatment, their medication remained unchanged prior to CTA.

Adverse events (AE) were defined as

contrast-related and technical- related.

AE related to contrast included bitter taste, erythema, nausea, vomiting, and anaphylactic shock. To reduce bias, warming sensation and bitter taste were considered physiological and were not included. They were evaluated after contrast administration and up to 24 hours following the examination since all patients were represented by hospitalized patients.

The technical related events were assessed immediately after contrast agent administration. The presence of extravasation of the contrast agent, misplacement of the catheter and air embolus were recorded.

Data normality was evaluated using a Kolmogorov-Smirnov test.

Continuous variables are expressed as mean +/- standard deviation (SD) if data has normal distribution or as median and interquartile range (IQR) if data is skewed.

Comparison of medians was made using Mann-Whitney tests, and correlation strength analysis was assessed using Spearman test.

All statistical calculations were performed using IBM SPSS Statistics 26, with a p-value <0.05 considered statistically significant.

RESULTS

Data from 697 examinations performed at one institution were retrospectively included in the study. The median patient age at the time of the scan was 199.00 days (range: 0 days to 17 years; IQR [15,1714.5]). Females accounted for 44.5% of the study population (n=310), while males were 55.5%, resulting in a male-to-female ratio of 1.29. The median male age was 245 days, IQR [15,2102]; was statistically significantly different ($P = 0.045$) from the median female age, which was 153 days, IQR [15,1097].

The median weight was 6.0 kilograms, IQR [3.4,15], while the median height was 65.00 centimeters, IQR [53,105].

The most common primary indications for the studies were vascular abnormalities - including aortic coarctation, ascending aortic ectasia, and aortic arch hypoplasia — as well as complex congenital heart malformations such as TOF (including double outlet right ventricle), transposition of the great arteries, and total anomalous pulmonary venous return.

Before surgical or interventional treatment, aortic coarctation, complex congenital heart malformations, and TOF accounted for 55.73% of all cases, representing 306 examinations of a total of 549. Following surgical correction, the most frequent indications remained similar, with aortic coarctation, Tetralogy of Fallot, and transposition of the great arteries comprising 60.81% of all cases (90 examinations out of 148).

When using peripheral access, the most frequent cannulation site was the left upper limb antecubital fossa, 265 cases (38.02%) followed by the right upper limb, 242 cases (34.72%). Scalp veins and inferior limb peripheral cannulas were used less frequently, representing less than 12.19% of the total sites (fig. 1).

A central line was used in 101 cases (14.49%), placed in the superior vena cava (72 cases), inferior cava vein tributaries (25 cases) or umbilical veins (4 cases).

Figure 1 illustrates the distribution of venous access sites and the size (gauge) of the devices used in patients. The x-axis indicates the location of the venous access. The y-axis shows the number of patients who received access to that site. The colors within the bars represent the size (gauge) and the type of catheter / cannula used.

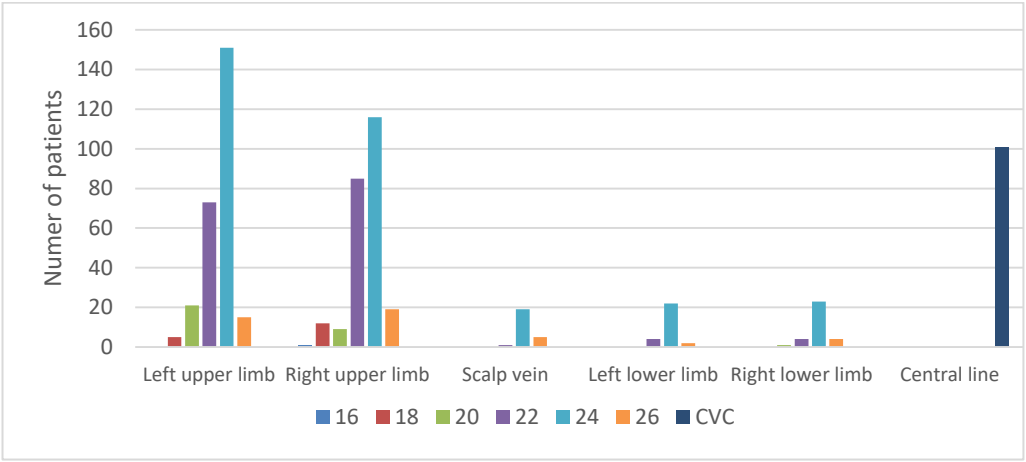

Fig. 1. Venous access sites and size (gauge)

As the gauge number increases (moving from a 16 gauge up to a 26 gauge and then a central line), the median flow rate consistently and significantly decreases, confirming that larger cannulas (lower gauge numbers) permit much higher flow rates. For example, the 18-gauge cannula shows the highest median flow-rate 2.5 and the largest range, IQR [0.9, 3.5], while the 24- and 26-gauge cannulas have the lowest median flow rate 0.8 and the least variability, IQR [0.8,1.0], demonstrating the critical impact of catheter diameter on intravenous fluid delivery speed. The central line is comparable with 24- and 26-gauge cannulas (fig. 2).

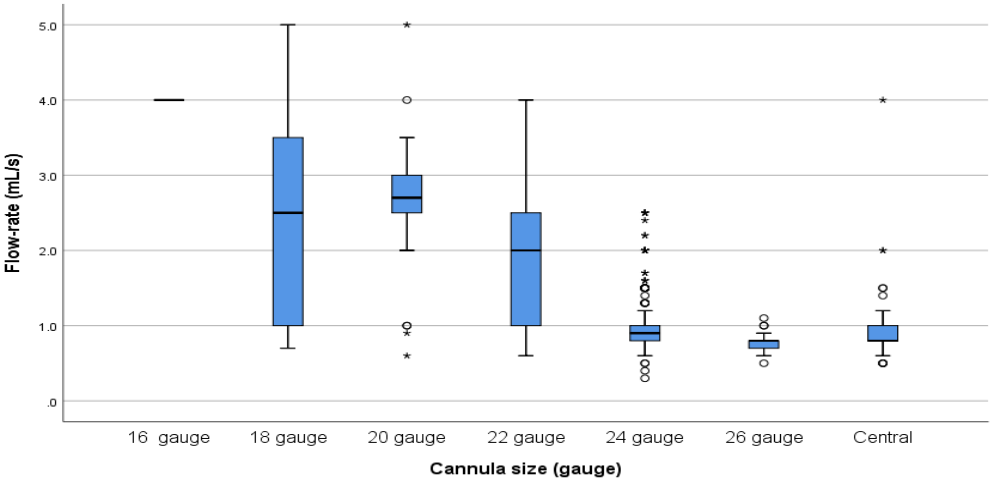

Fig. 2. Relation between flow-rate (mL/s) and cannula size (gauge)

In the second figure the asterisks indicate far out values, the central box represents the values from the lower to upper quartile (25 to 75 percentile) and the mid-

dle line represents the median. The vertical line extends from the minimum to the maximum value, excluding outside and far-out values, which are displayed as separate points (fig. 2).

Four allergic reactions and an anaphylactic shock with Iodixanol 320 were recorded. All cases are resolved favorably after medical treatment.

With peripheral cannulation, nine cases of subcutaneous extravasation of contrast media occurred (1.29%) with a 95% confidence interval ranging from 0.68%-2.44%. This narrow confidence interval suggests a low and stable rate of extravasation in the study population, indicating that the procedure was performed safely and consistently. They occurred while using 22 to 26 gauge, eight being placed in the upper limb and one in the lower limb, and without connection to the injection flow rate (between 0.6 mL/s and 2.5 mL/s) or the administered media (Iopromide 370, Iomeron 350 and Iodixanol 320) (tab. I).

TABLE I.

Extravasation cases, including injection site, cannula gauge, flow rate, and type of contrast agent used.

Extravasation	Place	Gauge	Flow mL/s	Agent
Extravasation 1	Left upper limb	26 gauge	0.6	Iopromide 370
Extravasation 2	Right lower limb	24 gauge	0.8	Iomeprol 350
Extravasation 3	Left upper limb	22 gauge	0.8	Iomeprol 350
Extravasation 4	Left upper limb	24 gauge	0.8	Iomeprol 350
Extravasation 5	Left upper limb	24 gauge	0.8	Iomeprol 350
Extravasation 6	Left upper limb	24 gauge	1	Iomeprol 350
Extravasation 7	Left upper limb	22 gauge	1	Iomeprol 350
Extravasation 8	Left upper limb	22 gauge	2.3	Iodixanol 320
Extravasation 9	Right upper limb	22 gauge	2.5	Iodixanol 320

The use of central line was not associated with incidents due to contrast medium injection, however, we report two cases of central venous catheter misplacement into the artery, which were detected immediately prior to the exam (2/101= 1.98% with a Wilson CI of 0.55%- 6.98%) and an injection incident, one air embolus (1/101= 1.01% with a Wilson CI of 0.19%-5.43%).

The Mann-Whitney U test showed no significant differences in injection flow rate between examinations with and without extravasation (1.18 mL/s vs 1.31 mL/s, $U = 2648.00$, $p = 0.447$), indicating no association between flow rate and extravasation occurrence.

Reactions were evaluated using the ACR-ESUR classification. Three cases of erythema and one case of nausea were observed, both classified as Grade 1 (minor reactions), as they were mild and self-limiting. A case of anaphylactic shock occurred, classified as Grade 3 (severe reaction), requiring immediate medical intervention (tab. II).

TABLE II.

Types of injected contrast agents and adverse reactions

Type of contrast agent	Erythema	Nausea/ Vomiting	Anaphylactic shock	Grand Total Cases
Iomeprol 350				387 (55.5%)
Ioversol 350	1			112 (16%)
Iopromide 370	1			122 (17.5%)
Iodixanol 320	1	1	1	76 (10.9%)
Total Number of Reactions	3 (0.45%)	1 (0.14%)	1 (0.14%)	697

Following the implementation of the universal premedication protocol in 2019, a distinct cessation of adverse reactions was observed. While the period between 2015 and 2019 showed an incidence of approximately 1.2 reactions per year, no contrast-related adverse events were recorded in the study population from 2020 onward. Technical events were in total 12 (12/697=1.72% with a 95% CI 0.75%-2.69%) distributed approximately 1.2/year (fig. 3).

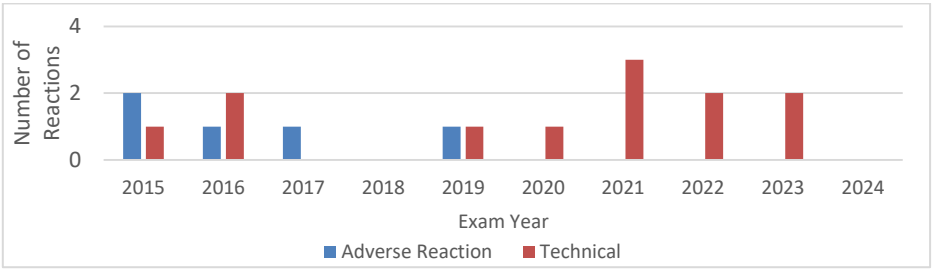

Fig. 3. Total number of incidents per year

Figure 3 presents annual distribution of contrast-related adverse events and technical complications (2015-2024). Technical events occurred at a rate of approximately 1.2 per year. No contrast-related adverse reactions were recorded from 2020 onward, coinciding with the introduction of the universal premedication protocol.

DISCUSSION

Using power injectors with small cannulas, especially via non-implanted central venous catheters, is challenging. Catheter type, injection rate, pre-warming, and pressure affect outcomes, and patient factors must guide decisions.

When the contrast agent was used, tried and adjusted to the size and quality of the vein, neither the extravasation rates nor the contrast reaction frequencies were significantly different from those reported for CT angiography. The extravasation rate was 1.29% (95% CI: 0.68%-2.44%) in our group, 0.36% (95% CI: 0.10%-1.31%) in Amaral et al. and 0.74% (95% CI: 0.47%-1.17%) in Barrera et al. The overlapping 95% CIs (0.68%-2.44%, 0.10%-1.31, 0.47%-1.17) suggest no statistically significant difference between studies. Amaral et al. reported that the risk of extravasation correlated with high

injection rate and pressure. Although, in our examination, the Mann-Whitney U test showed no significant differences in injection flow rate between examinations with and without extravasation (1.18 mL/s *vs.* 1.31 mL/s, U = 2648.00, p = 0.447), indicating no association between flow rate and extravasation occurrence (22, 26-30).

Our center's treatment yielded a few minor adverse reactions related to contrast agent (0.6% with a Wilson CI of 0.24%-1.50%) and one anaphylactic shock (0.14% with a Wilson CI of 0.02%-0.80%), when using low-osmolar iodinated contrast media, all which resolved favorably following conservative treatment; in this regard our experience stays in accordance to previously reported data

When speaking about the limitations of the study, one was the relatively small sample size, and all data was collected from a single center. Many examinations were performed under sedation, so some contrast-related incidents may have gone unnoticed. Children may also have difficulty reporting reactions. Due to the retrospective design, only adverse events documented in radiology reports were collected and late complications such as kidney failure or central line infections could not be assessed. Moreover, over the years, the protocol has undergone several modifications; therefore, its heterogeneity may have influenced the results.

CONCLUSIONS

In this nine-year cohort, pediatric congenital heart disease CTA demonstrated low rates of technical and contrast-related complications. Peripheral extravasation was infrequent and self-limited. Central venous access was associated with rare line placement incidents, underscoring the importance of pre-scan verification. Further stratified analyses suggest that universal premedication may contribute to low rates of hypersensitivity. Overall, the procedure is safe for these pediatric CHD patients, as also observed in similar studies (28, 31, 32).

SEGMENTAL VASCULAR BURDEN AND OUTCOMES IN DIABETIC *VS.* NON-DIABETIC CHRONIC LIMB-THREATENING ISCHEMIA AFTER ENDOVASCULAR REVASCULARIZATION (Abstract): Peripheral artery disease (PAD) progressing to chronic limb-threatening ischemia (CLTI) is associated with high morbidity and limb loss. Diabetes mellitus (DM) significantly influences disease distribution and clinical outcomes. The Bollinger score, GLASS classification, and WIfI staging are complementary tools for assessing anatomical burden and limb threat. This study aimed to analyze the relationships between these scoring systems in diabetic CLTI, with particular focus on infra-popliteal versus global anatomical evaluation. **Materials and methods**: This single-center retrospective study included 136 patients with CLTI undergoing endovascular revascularization between May 2021 and May 2023. Baseline characteristics, angiographic severity, WIfI stage, Bollinger scores (whole limb, above- and below-knee), GLASS staging (global, femoropopliteal and infra-popliteal), and outcomes (technical success, bypass conversion, major amputation, and one-year mortality) were analyzed. **Results**: Patients were divided into diabetic (DM, n=85) and non-diabetic (NDM, n=51) groups. Diabetic patients more frequently presented with infra-inguinal stenoses >50% (55.3% *vs.* 35.3%, p=0.024) but fewer complete occlusions (83.5% *vs.* 96.1%, p=0.028). WIfI stage 1 was more common in the DM group (54.1% *vs.* 33.3%, p≈0.08). Bollinger scores were lower in diabetics for the whole limb (30.07±16.34 *vs.* 36.78±16.09, p=0.018) and below-knee segment (20.53±15.88 *vs.* 26.86±13.93, p=0.015). **Conclusions**: Diabetic CLTI is characterized by a distal angiographic pattern with predominant infra-popliteal stenoses and lower additive Bollinger scores. Segmental infra-popliteal assessment showed stronger clinical relevance than global evaluation, with below-knee Bollinger and GLASS infra-popliteal stages most closely associated with WIfI severity. These findings support a segment-focused approach in endovascular planning for diabetic patients.

INTRODUCTION

Peripheral artery disease (PAD) progressing to chronic limb - threatening ischemia (CLTI) is associated with high

morbidity, limb loss, and mortality, particularly in patients with diabetes mellitus (DM). Over the past two decades, endovascular therapy has become the first-line strategy for most infra-inguinal lesions, supported by contemporary guidelines and randomized evidence demonstrating lower peri-procedural risk compared with open bypass in appropriately selected patients (1-4). Percutaneous transluminal angioplasty remains the cornerstone of treatment, with adjunctive stenting used in selected cases of residual stenosis, flow-limiting dissection, or complex lesions.

Diabetes mellitus significantly alters the anatomical and biological characteristics of PAD. Diabetic arteriopathy is typically distal, multi-segmental, and frequently associated with calcification, impaired collateralization, and microvascular dysfunction. This phenotype results in more severe infra-popliteal involvement and a predominance of stenotic rather than extensive occlusive lesions. Mechanistically, medial arterial calcification, microangiopathy, and endothelial dysfunction have been identified as key contributors, influencing both procedural feasibility and long-term durability of endovascular interventions (5-7).

To standardize evaluation and guide clinical decision-making, complementary scoring systems are widely used. The Society for Vascular Surgery WIfI classification assesses wound extent, ischemia, and foot infection to estimate amputation risk and the potential benefit of revascularization (8, 9). The Bollinger score provides a semi-quantitative assessment of segmental atherosclerotic burden across the lower limb arterial tree (10-12). The Global Limb Anatomic Staging System (GLASS) integrates femoropopliteal and infra-popliteal disease complexity to predict technical success and durability of revascularization strategies (1, 13, 14). Together, these tools offer a comprehensive framework combining clinical severity, anatomical burden, and procedural complexity.

Clinical outcomes in CLTI are influenced by multiple lesion- and patient-related factors, including lesion type (stenosis versus occlusion), lesion length, multilevel disease, runoff status, and comorbidities such as DM and chronic kidney disease. These factors directly affect technical success, patency, and limb salvage, highlighting the importance of standardized assessment and reporting (1, 4, 15). However, comparative data evaluating diabetic versus non-diabetic CLTI using integrated scoring systems (WIfI, Bollinger, and GLASS) remain limited in Eastern European populations.

Therefore, this study aimed to analyze the characteristics of diabetic patients with CLTI undergoing endovascular revascularization and to evaluate the relationships between WIfI stage, Bollinger score (whole limb; above- and below-knee), and GLASS classification (global, femoropopliteal, and infra-popliteal), with particular emphasis on segmental infra-popliteal assessment compared with global limb evaluation.

MATERIALS AND METHODS

Study design. This was a single-center, retrospective observational study conducted at the Vascular Surgery Clinic of Sf. Spiridon County Clinical Emergency Hospital Iași, Romania. The study included consecutive patients diagnosed with CLTI who underwent endovascular revascularization between May 2021 and May 2023. The study protocol complied with institutional and ethical standards, and all patients pro-

vided informed consent for the procedures performed.

Patients. A total of 136 patients with CLTI were included. Patients were stratified into two groups based on the presence of diabetes mellitus: diabetic (DM, n=85) and non-diabetic (NDM, n=51). CLTI was defined as ischemic rest pain lasting more than two weeks, with or without tissue loss. Diabetes mellitus was defined based on documented medical history, ongoing antidiabetic treatment, or HbA1c ≥6.5% at admission or during hospitalization. Patients with acute limb ischemia, isolated aorto-iliac disease, recent surgical bypass, or without indication for revascularization were excluded.

Data collection. Baseline demographic characteristics, cardiovascular risk factors, and comorbidities were recorded. Angiographic evaluation was performed using digital subtraction angiography. The Bollinger score was calculated as a segmental additive measure of atherosclerotic burden, based on lesion severity and distribution (10-12). Scores were obtained for the whole limb, as well as for above-knee and below-knee segments. The GLASS classification was used to assess femoropopliteal and infra-popliteal lesion complexity and to determine overall limb staging (1, 13, 14). Clinical severity was evaluated using the Society for Vascular Surgery WIfI classification, according to established criteria (8, 9). WIfI staging was reconstructed retrospectively based on available clinical and hemodynamic data.

Endpoints. The primary endpoint was technical success, defined as restoration of inline flow to at least one pedal artery with less than 30% residual stenosis on completion angiography. Secondary endpoints included early (30-day) limb-related outcomes - major amputation, conversion to surgical bypass, and repeat revascularization - as well as late outcomes, defined as one-year all-cause mortality.

Statistical analysis was performed using *SPSS version 29*. Continuous variables were expressed as mean ± standard deviation (SD) and compared using t-Student's test or the Mann-Whitney U test, depending on data distribution. Categorical variables were expressed as absolute numbers and percentages and compared using the χ^2 test or Fisher's exact test, as appropriate. Correlations between scoring systems were assessed using Spearman's rank correlation coefficient. Agreement between scoring classifications was evaluated using Cohen's kappa coefficient. Logistic regression analysis was performed to explore predictors of technical failure; detailed model outputs are not presented, as they fall beyond the primary scope of the present study. Variables with potential clinical relevance or statistical significance in univariate analysis were included in the multivariate model. Model performance was evaluated using the Hosmer-Lemeshow goodness-of-fit test and Nagelkerke R^2. Statistical significance was defined at $p < 0.05$.

RESULTS

Baseline characteristics. A total of 136 patients with CLTI were included in the study, of whom 62.5% (n=85) had diabetes mellitus. Baseline clinical characteristics are presented in first table.

The two groups were comparable in terms of age and sex distribution, with a mean age of approximately 70 years in both groups (p=0.737). Urban residence was significantly more frequent among diabetic patients (72.9% *vs.* 49.0%, p=0.005). The prevalence of hypertension (85.9% *vs.*

74.5%), chronic kidney disease (18.8% *vs.* 13.7%), and prior stroke (11.9% *vs.* 3.9%) was higher in the diabetic group; however, these differences did not reach statistical significance.

Angiographic findings and WIfI stages. Angiographic characteristics and WIfI stages are summarized in table II.

TABLE I.
Baseline characteristics of patients

Parameter	NDM Group (n=51)	DM Group (n=85)	p-value
Female, n(%)	12 (23.5)	27 (31.8)	0.304
Urban residence, n (%)	25 (49.0)	62 (72.9)	0.005**
Age, years (mean ± SD)	69.78±11.38	69.89±8.57	0.737
Hypertension, n (%)	38 (74.5)	73 (85.9)	0.097
Obesity, n (%)	4 (7.8)	13 (15.3)	0.203
Heart failure, n (%)	17 (33.3)	24 (28.2)	0.531
Atrial fibrillation, n (%)	15 (29.4)	16 (18.8)	0.154
Prior mi, n (%)	2 (3.9)	7 (8.2)	0.483
Chronic coronary syndrome, n (%)	8 (15.7)	17 (20.0)	0.530
Cardiomyopathy, n (%)	1 (2.0)	5 (5.9)	0.410
Dilated cardiomyopathy, n (%)	4 (7.8)	4 (4.7)	0.473
Chronic kidney disease, n (%)	7 (13.7)	16 (18.8)	0.443
Prior stroke, n (%)	2 (3.9)	10 (11.9)	0.210

TABLE II.
Angiographic severity according with WIfI stages in the diabetes mellitus (DM) and non-diabetes (NDM) groups.

Variable	NDM Group (n=51)	DM Group (n=85)	p-value
>50% stenosis, n (%)	18 (35.3)	47 (55.3)	0.024*
Any occlusion, n (%)	49 (96.1)	71 (83.5)	0.028*
WIfI stage 1, n (%)	17 (33.3)	46 (54.1)	0.083+
Stents present, n (%)	11 (21.6)	20 (23.5)	NS

*NS non-significant

Patients in the diabetic group more frequently presented with stenoses greater than 50% compared with non-diabetic patients (55.3% *vs.* 35.3%, p=0.024). In contrast, complete occlusions were less frequent among diabetics (83.5% *vs.* 96.1%, p=0.028). WIfI stage 1 was more common in the diabetic group (54.1% *vs.* 33.3%),

although this difference did not reach statistical significance (p≈0.08). The presence of stents was similar between groups.

Bollinger and GLASS scores

Bollinger and GLASS scores are presented in table III.

TABLE III.

The Bollinger score in the DM group *vs.* the NDM group

Parameter	NDM Group	DM Group	p-value
Bollinger whole leg, mean ± SD	36.78±16.09	30.07±16.34	0.018*
Bollinger above knee, mean ± SD	9.92±8.01	9.54±6.96	0.941
Bollinger below knee, mean ± SD	26.86±13.93	20.53±15.88	0.015*
Glass global: stage 1, n (%)	23 (45.1)	28 (32.9)	NS
Glass global: stage 2, n (%)	18 (35.3)	35 (41.2)	NS
Glass global: stage 3, n (%)	10 (19.6)	22 (25.9)	NS

Diabetic patients exhibited lower Bollinger scores for the whole limb (30.07±16.34 *vs.* 36.78±16.09, p=0.018) and for the below-knee segment (20.53± 15.88 *vs.* 26.86±13.93, p=0.015). No significant differences were observed for above-knee scores. Global GLASS staging showed a similar distribution between the two groups, with no statistically significant differences across stages.

Outcomes of revascularization. Early limb-related outcomes and one-year mortality are presented in table IV.

TABLE IV.

Success rate in the DM group *vs.* NDM group

Outcome	NDM Group (n=51)	DM Group (n=85)	p-value
Technical success, n (%)	37 (72.5)	64 (75.3)	0.71
Bypass, n (%)	6 (11.8)	10 (11.8)	1.00
Major amputation, n (%)	2 (3.9)	8 (9.4)	0.32
Death, n (%)	1 (2.0)	3 (3.5)	1.00

Technical success was achieved in 74.3% of cases, with no significant difference between diabetic and non-diabetic patients (75.3% *vs.* 72.5%, p=0.71). Bypass conversion rates were identical in both groups (11.8%). Major amputation occurred more frequently in the diabetic group (9.4% *vs.* 3.9%), without statistical significance (p=0.32).

In-hospital mortality was low and comparable between groups (3.5% *vs.* 2.0%, p=1.00).

Correlations between scoring systems. Correlations between WIfI stage, Bollinger score, and GLASS classification are presented in table V.

TABLE V.

Correlations between WIfI stage, Bollinger score and GLASS classification.

Correlation	ρ	p-value
WIfI ↔ Bollinger (whole leg)	0.290	<0.001
WIfI ↔ GLASS (global)	0.173	0.044
Bollinger (whole leg) ↔ GLASS (global)	0.643	<0.001
Above - knee: Bollinger ↔ GLASS-FP	0.762	<0.001
Below - knee: WIfI ↔ Bollinger-IP	0.266	0.002
Below - knee: Bollinger-IP ↔ GLASS-IP	0.713	<0.001

A strong correlation was observed between Bollinger whole-limb score and global GLASS stage (ρ=0.643, p<0.001). Moderate correlations were identified between WIfI stage and Bollinger score (ρ=0.290, p<0.001), and a weaker correlation between WIfI stage and GLASS classification (ρ=0.173, p=0.044). At the segmental level, the strongest association was observed between infra-popliteal Bollinger score and GLASS infrapopliteal stage (ρ=0.713, p<0.001).

Correlations heatmap illustrating these relationships are shown in the first figure.

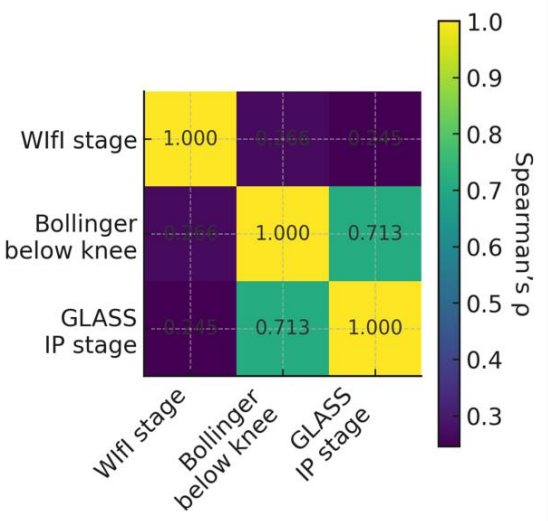

Fig. 1. Spearman's correlation heatmap (ρ) between WIfI stage, infra-popliteal Bollinger score (below-knee burden), and GLASS infra-popliteal (IP) stage.

DISCUSSION

This study provides a comparative evaluation of diabetic and non-diabetic patients with CLTI undergoing endovascular revascularization, integrating 3 complementary scoring systems: WIfI, Bollinger, and GLASS. The combined use of these tools allowed a structured assessment of clinical

severity, anatomical burden, and procedural complexity. Our findings confirm that diabetes significantly alters the angiographic pattern of peripheral arterial disease. Patients in the DM group more frequently presented with infra-inguinal stenoses >50% and fewer complete occlusions, accompanied by lower Bollinger scores for both the whole limb and the below-knee segment. This pattern reflects the known pathophysiology of diabetic arteriopathy, characterized by diffuse, calcific, predominantly distal disease with relative preservation of luminal continuity (15, 20-22).

At first glance, the lower Bollinger scores observed in diabetic patients may appear contradictory to the established concept of diffuse and severe disease in diabetes. However, this discrepancy likely reflects a limitation of occlusion-weighted scoring systems, which may underestimate disease severity in the presence of heavily calcified but patent distal vessels (23-25). Thus, in diabetic CLTI, anatomical burden is not fully captured by additive occlusion-based metrics alone. In contrast, patients in the non-DM group more frequently exhibited proximal and occlusive lesions, consistent with a classical macroatherosclerotic pattern. These differences underline the importance of considering disease phenotype when interpreting angiographic scores and planning revascularization. The observed trend toward a higher prevalence of WIfI stage 1 in diabetic patients suggests a potential mismatch between clinical presentation and anatomical severity. In this population, neuropathy and early-stage tissue loss may lead to lower wound grades despite advanced an infrapopliteal disease. This highlights the limitation of relying solely on clinical staging and supports the need for detailed distal anatomical assessment. A key finding of our study is the strong correlation between infra-popliteal Bollinger and GLASS scores ($\rho = 0.713$), which was higher than correlations observed at the global or femoropopliteal level. This reinforces the central role of the infra-popliteal compartment in determining both anatomical complexity and clinical severity in CLTI, particularly in diabetic patients. Similar observations have been reported in contemporary studies emphasizing the predominance of distal disease in diabetes (15, 20-22). The agreement analysis further supports this concept, showing moderate-to-substantial concordance between Bollinger and GLASS overall, with stronger agreement in the DM group. In contrast, the weak association between femoropopliteal GLASS stages and WIfI underscores that proximal anatomy alone does not adequately reflect limb threat. The modest agreement between infra-popliteal GLASS and WIfI in diabetic patients suggests that distal disease has a more direct clinical impact. These findings are consistent with the pathophysiological model proposed by Ferraresi *et al*., in which small artery disease (SAD) and below-the-ankle (BAD) involvement play a critical role in tissue perfusion, even after technically successful revascularization (27). Histopathological studies further support the presence of diffuse distal obstruction and microvascular dysfunction in CLTI, particularly in diabetic limbs (28). In this context, angiographic scoring systems may act as indirect markers of perfusion impairment rather than direct measures of microcirculatory status.

From a procedural standpoint, technical success rates were comparable between groups, confirming that diabetes does not preclude effective endovascular revascular-

ization. However, clinical outcomes tended to be less favorable in the DM group, with higher rates of major amputation and slightly increased mortality. Although not statistically significant, these trends are consistent with previous reports highlighting the influence of systemic factors such as infection, neuropathy, and impaired wound healing on outcomes in diabetic CLTI (17, 29). The relationship between lesion characteristics and procedural success also differed between groups. While stent implantation was associated with higher technical success in the non-DM group, this effect was less evident in diabetic patients, possibly due to smaller vessel caliber, diffuse disease, and increased calcification. These findings support a more selective use of stenting in infra-popliteal disease, in line with contemporary endovascular strategies.

Overall, the integration of WIfI, Bollinger, and GLASS provides a comprehensive framework for CLTI evaluation. WIfI reflects clinical severity, Bollinger quantifies anatomical burden, and GLASS estimates procedural complexity. Their combined use allows a more accurate characterization of disease and may improve decision-making in endovascular planning. The strong segmental correlations observed below the knee support the routine inclusion of infra-popliteal scoring, particularly in diabetic patients. Our results are consistent with prior studies, including BASIL and subsequent analyses, which demonstrated the prognostic value of anatomical scoring systems in CLTI (12).

At the same time, our findings highlight potential limitations of global scoring approaches and support a shift toward segment-focused evaluation, especially in populations with a high prevalence of diabetes.

From a clinical perspective, recognizing the infra-popliteal predominance of diabetic PAD may facilitate earlier intervention, optimize revascularization strategies, and improve multidisciplinary management of CLTI.

A final aspect to consider is the retrospective, single-center design, which may limit generalizability. In addition, WIfI staging was reconstructed retrospectively and long-term outcomes were not systematically assessed. Despite these limitations, the study provides relevant insights into the segmental distribution of disease and the complementary role of integrated scoring systems in diabetic CLTI.

CONCLUSIONS

In diabetic patients with CLTI, anatomical evaluation may benefit from moving beyond global limb scoring toward segmental infra-popliteal assessment. When planning endovascular revascularization, below-knee Bollinger burden and GLASS infra-popliteal staging, integrated alongside WIfI, better reflect distal disease severity and procedural complexity. These findings support a segment-focused approach to endovascular management in diabetic CLTI.

ACKNOWLEDGEMENTS

The authors thank the medical and nursing staff of the Vascular Surgery Clinic, Sf. Spiridon County Clinical Emergency Hospital Iași, for their support in patient care and data collection.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding regarding this scientific research.

ASYMPTOMATIC COMPLEX TESTICULAR NEOPLASIA ASSOCIATED WITH ORCHIEPIDIDYMITIS-CASE REPORT (Abstract): Testicular germ cells tumors (TGCTs) are rare (2-3 new cases per 100,000 men per year) accounting for 1-2% of male malignancies and ranking fourth among genitourinary cancers. Testicular cancer is the most common cancer in young men 15 to 35-year-old. With approximately 50% of the TGCTs being pure seminomas and 50% non-seminomas, "radical orchiectomy" provides the histological diagnosis and should be performed before any further treatment, unless the clinical situation requires immediate chemotherapy in patients with a clear germ cell malignancy based on elevated tumor markers. Any testicular mass of uncertain ranking must be explored by the inguinal approach to verify or exclude malignancy. We present the case of a 30-year-old patient admitted to the Urology unit of the "Dr. C.I. Parhon" Clinical Hospital for pain in the right hemiscrotum for two weeks. Physical examination revealed the increase in size and local inflammatory changes of the right hemiscrotum. Later during hospital stay, the patient mentioned that the hemiscrotum had been progressively increasing in size over the past 6 months. An ultrasound exam was performed, and serum tumor markers were determined. Based on the results, the patient underwent radical orchiectomy by inguinal approach. **Keywords**: ORCHIEPIDIDYMITIS, GERM CELL TUMOR, TREATMENT.

Testicular germ cells tumors (TGCTs) are divided into two categories: seminomas and nonseminomas. The last category can subsequently be divided into choriocarcinoma, teratoma, embryonal cell carcinoma and yolk-sac tumor. Risk factors for TGCT are: family history, cryptorchidism, testicular dysgenesis, Klinefelter syndrome, Down syndrome, feminized testicle syndromes, persistent Müllerian duct syndrome and hermaphroditism (1).

The serum tumor markers alpha-fetoprotein (AFP) (≤5.80 IU/mL or <10 ng/mL), human chorionic gonadotropin (hCG) (<2.6 mIU/mL) and lactate dehydrogenase (LDH) (135-225 U/L) are essential in determining the presence of tumor and its prognosis, and for assessing the postoperative outcome (1). The recommended treatment for TGCTs is radical orchiectomy (2).

CASE REPORT

We present the case of R.C., a 31-year-old male patient admitted to the Urology Department of the "Dr. C.I. Parhon" Clinical Hospital from Iasi for fever and shivers which started a few days before his admission and pain in and increase in size of the right hemiscrotum over the last two weeks.

His personal medical history included: hepatic steatosis, ulcerative pancolitis in the remission phase (treated with Infliximab) and stage I-II pulmonary sarcoidosis (on corticotherapy). Physical examination revealed class II obesity, painful right hemiscrotum both spontaneously and on palpation, warm and with overlying congested tissue. Laboratory tests showed no biochemical or blood count changes suggestive for the febrile syndrome. Based on the collected data, our first diagnostic supposition was "suppurative right orchiepididymitis" and the patient was given Cefuroxime 0.5g, the fever diminishing within the first 24 hours.

Later during his admission to the Urology Clinic, the patient mentioned that his right hemiscrotum had been slowly increasing in size over the past 6 months. The scrotal ultrasound revealed an inhomogeneous right testicle (fig. 1), increased in size, with imprecise limits and negative Doppler signal.

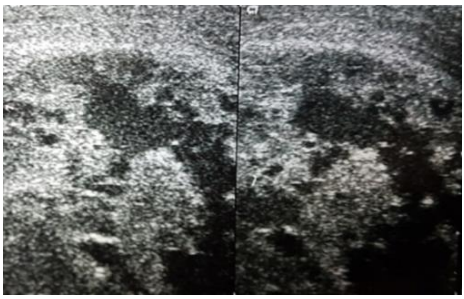

Fig. 1. Ultrasonography of the right hemiscrotum.

This result was suggestive for a highly disorganized testicular parenchyma either due to suppuration or neoplastic process. Tumor markers AFP, *hCG* and *LDH* were determined as part of the preliminary diagnosis. The blood results came back positive: AFP – 689.8 IU/mL, hCG - 10.6 mIU/mL, LDH - 288 U/L. As a result, the surgical intervention for the drainage of the supposed suppuration was canceled to prevent the tumor from metastasizing.

The patient was discharged on Cefuroxime 0.5g for the treatment of orchiepididymitis with the recommendation to return after two weeks to undergo radical orchiectomy. *Abdominal and pelvic CT scan* for the detection of lymphadenopathy was not performed due to the lack of certainty in differentiating inflammatory from metastatic lymphadenopathies. In this case, waiting for the disappearance of inflammatory lymphadenopathies might have taken long enough for the testicular tumor to disseminate.

After two weeks the patient was readmitted for surgical intervention. With the patient in dorsal decubitus, under general anesthesia and orotracheal intubation, a 10-cm oblique incision just 2 cm superiorly and parallel with the inguinal ligament was performed. After the section of the muscular and aponeurotic layers and dissection of the fascia of the external oblique muscle, the right spermatic cord (or funiculus spermaticus) was exposed. The spermatic cord was not isolated with ease, due to the adherences resulted from the previous inflammation.

The spermatic cord was clamped (fig. 2); the testicle was ascended through the inguinal canal and brought to surface through the surgical wound.

The funiculus spermaticus was sectioned

and sutured with 2 double suture wires. Surgical hemostasis was performed, the anatomical defects were repaired, the surgery ending with the placement of sterile bandage.

Fig. 2. The clamped spermatic cord

Gross examination described an enlarged testicle due to a low-consistency and heterogeneous mass, which was occupying almost the entire testicular parenchyma and was invading the tunica albuginea (fig. 3).

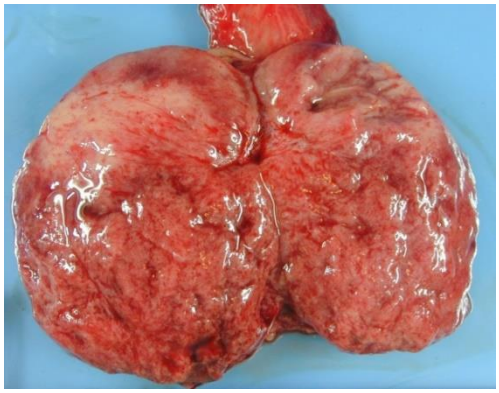

Fig. 3. The macroscopic appearance of the tumor

Microscopic examination highlighted germ cell tumor proliferation, with necrosis and hemorrhagic areas, which was invading the testicle and tunica albuginea. The microscopic appearance had a complex pattern: embryonal carcinoma with areas of mature and immature teratoma, associated with areas of seminoma (fig. 4-5).

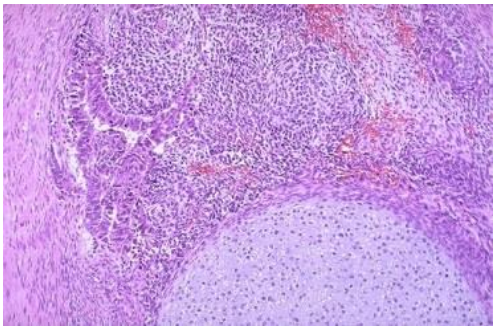

Fig. 4. Microscopy - embryonal carcinoma and teratoma

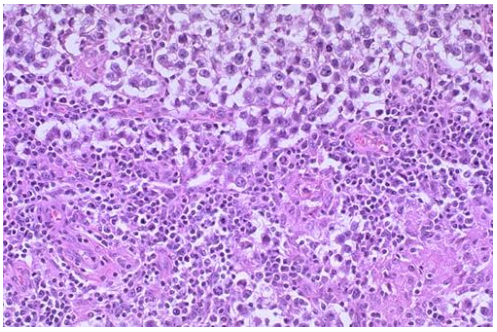

Fig. 5. Microscopy - embryonal carcinoma and seminoma

The diagnosis was positive for pT2NxMx "Mixed germ cell tumor".

The patient's postoperative outcome was favorable and was discharged after three days and instructed to have the tumor marker levels determined after three and six postoperative weeks and an *abdominal and pelvic CT scan* six weeks postoperatively. After three weeks there was a decrease in tumor marker levels: AFP 34.60 IU/mL, hCG 4.6 mIU/mL, LDH 184 U/L.

After six weeks postoperatively, although the AFP reached normal blood levels (3.13 IU/mL) and LDH was still within normal range, the hCG levels were increasing (8.6 mIU/mL). The CT exam at five months postoperatively revealed multiple mediastinum and abdominal lymphadenopathies (epiphrenic, epigastric, interportocaval, later aortic bilateral, peripancreatic), bilateral common iliac lymphadenopathies (left side = 12/27 mm, right side = 18/14 mm) and an adenopathic conglomerate located in the paraaortic lymph nodes, 52/32/60mm in size. At five months postoperatively, the tumor markers continued to rise (AFP=41.48 ng/mL, hCG=22.1 mIU/mL, LDH=217 U/L). Following these results, the patient was admitted to the Oncology Unit, where he received, up until seven months postoperatively, 4 cycles of the recommended chemotherapeutic "BEP Protocol" (Bleomycin 30 Units x 3 cycles, Etoposide 240 mg x 4 cycles, Cisplatin 80 mg x 4 cycles) (fig. 6), during which he developed stage IV neutropenia.

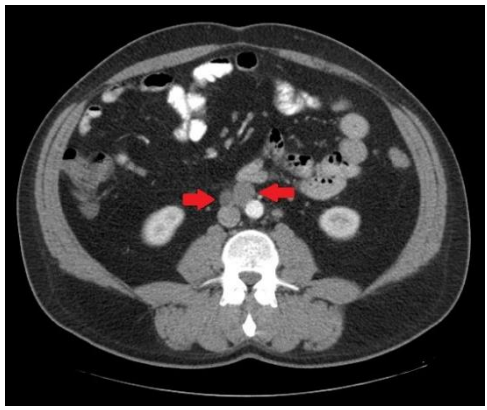

Fig. 6. Interaortocaval adenopathies

A second CT scan at 8 months postoperatively revealed a slight decrease in size of the abdominal and mediastinal adenopathies, suggestive for a partial response to the chemotherapy treatment. The patient is now regularly followed-up at the Oncology and Urology Units.

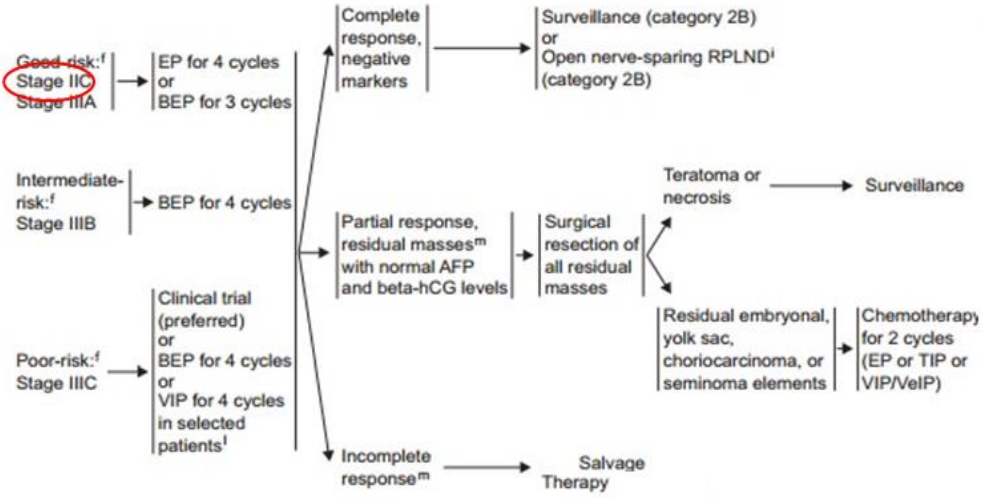

Fig. 6. Stage IIC postoperative recommended treatment

TABLE I

TNM Classification of Seminoma Testicular Cancer

T	Description	N	Description	M	Description
x	Primary tumor cannot be assessed	x	Regional lymph nodes cannot be assessed	0	No distant metastasis
0	No evidence of primary tumor	0	No regional lymph node metastasis	1	Distant metastasis
is	Intratubular germ cell neoplasia	1	Metastases to single or multiple lymph nodes, each < 2 cm in size	1a	Nonregional nodal or pulmonary metastasis
1	Tumor limited to the testis and epididymis or tumor invasion into the tunica albuginea only	2	Metastases to single or multiple lymph nodes, >2 cm but < 5 cm in size	1b	Distant metastasis other than to nonregional lymph nodes and lungs
2	Tumor extending through the tunica albuginea with involvement of the tunica vaginalis	3	Metastases to lymph node, >5 cm in greatest dimension		
3	Tumor invades the spermatic cord				
4	Tumor invades the scrotum				

DISCUSSION

Considering all the previous information, the patient was diagnosed with cT2N3M0 (tab. I), S1 (tab. II), stage IIC (tab. III) (4) testicular cancer. The particularity of the case is how a painful orchiepididymitis revealed a hidden neoplasia by forcing the patient to see a urology specialist, just like in a similar case reported by A. Baletti et al. (6), and how the associated pathology changed the patient management. Although the standard management in neoplasia is a preoperative CT/IRM scan to identify any lymphatic or extra lymphatic lesion suspected of being a metastasis, in our patient's case the preoperative CT scan was abandoned due to the existing orchiepididymitis, which caused inflammatory lymphadenopathies.

Combining surgical and chemotherapy treatment, stage IIC seminomas are considered as having a good prognosis (1) and after the chemotherapy treatment is completed, the serum tumor markers are measured, and a thoraco-abdominopelvic CT scan is performed.

If the residual tumor mass is absent and the tumor markers are within the normal range, the patients require only follow-up, but if the tumor mass persists, like in our patient, a PET scan is recommended (5). A positive PET scan requires a biopsy to be performed, followed by surgical excision or radiotherapy. On the other hand, a negative PET scan requires no further procedure.

TABLE II

Serum levels of tumor markers

	LDH (U/L)	hCG (mUI/mL)	AFP (ng/mL)
SX	-	-	-
S0	Normal	Normal	Normal
S1	<1.5x normal	<5000	<1000
S2	1,5-10x normal	5000-50000	1000-10000
S3	>10x normal	>50000	>10000

CONCLUSIONS

Our paper presented the case of a young patient with an asymptomatic testicular germ cell tumor identified and later diagnosed during his hospitalization in the Urology department for another disease: acute orchiepididymitis on a tumoral testicle. If this inflammatory disease had not occurred, the tumor would have developed for a long period of time without any type of symptom, in which case it might have been identified only after systemic metastases might have occurred. Our paper also presents the investigations, as well as the surgical and medical treatments our patient underwent since the diagnosis.

CARDIOVASCULAR RISK IN RHEUMATOID ARTHRITIS. CASE REPORT (Abstract): We present the case of an obese patient with diabetes, hypertension, and dyslipidemia diagnosed 12 years ago with rheumatoid polyarthritis, non-responding to disease-modifying antirheumatic drugs (DMARDs) and anti-TNF antibodies who developed symptomatic episodes of tachyarrhythmia with important prognostic consequences. Cardiovascular risk assessment and the adoption of cardiovascular disease prevention strategy are integral part of the management of the patient with rheumatoid polyarthritis. **Keywords**: RHEUMATOID POLYARTHRITIS, DIABETES MELLITUS, CARDIO-VASCULAR RISK, BIOLOGICAL THERAPY, ARRHYTHMIA.

The diseases of the connective tissue are characterized by a complex multifactorial etiology and pathogenesis. Mortality and cardiovascular morbidity are higher in individuals with rheumatoid polyarthritis (RP) compared to the general population. Rheumatoid polyarthritis is an independent risk factor for cardiovascular disease. The degree of disease activity in RP is directly correlated with the cardiovascular risk (1). The early and aggressive treatment of RP reduces the rate of cardiovascular events. The association of therapy with statins and angiotensin converting enzyme inhibitors reduces the cardiovascular risk in patients with RP (2).

CASE REPORT

We present the case of a 57-year-old rural patient diagnosed with stage 4 seropositive rheumatoid polyarthritis and Steinbrocker class III functional capacity at the age of 45; the patient was initially treated with DMARDs (methotrexate and leflunomide) and corticosteroids, discontinued due to the diagnosis of pulmonary fibrosis; he then received biological therapy with infliximab, discontinued following the detection of some axillary lymphadenopathies (complex workup confirming they were of inflammatory type in the context of the collagen disease), later switched

to rituximab, with therapeutic response and a decrease in disease activity scores. The patient presented to the hospital for dyspnea on light-moderate exertion and palpitations with onset approximately 24 hours earlier, with irregular, fast heartbeats following prolonged high-intensity physical activities. He associated the traditional risk factors for coronary disease – diabetes mellitus, dyslipidemia, obesity, arterial hypertension.

Physical examination showed: good general health, absence of fever, conscious, third-degree obesity (BMI=41.20 kg/m^2), gynecomastia (fig. 1), lipodermatosclerosis, SpO_2=97% on room air, BP=160/100 mmHg, ventricular rate = 65 beats/minute, rhythmical heart noises, aortic atheromatosis, abdominal panniculus adiposus mobile with breathing, sensitive to palpation in the right-side hypochondrium, without signs of peritoneal irritation, hepatomegaly located 2 cm below the costal margin. Examination of the musculoskeletal system revealed: peripheral algofunctional syndrome (irreducible flexum of the left elbow at 10 degrees), „rheumatoid hand“ appearance with bilateral tumefaction of radiocubitocarpal joint and metacarpophalangeal joints II-III, bilateral swan neck deformity of the middle finger, bilateral Z-deformity of the thumb“, radial deviation of the carpal bones and ulnar deviation of fingers, atrophy of the dorsal interosseous muscles, bilateral tumefaction of the knee with liparthritis, without local warmth, cracking upon movement, discrete bilateral tumefaction of the tibiotarsal joint, bilateral deforming arthrosis of the metatarsophalangeal joint of the big toe, „rheumatoid foot“ appearance.

Electrocardiogram findings: pauci symptomatic episodes of bradycardia-tachycardia – polymorphic extrasystolic ventricular arrhythmia expressed through doublets, ventricular tachycardia phases/beats (fig. 2). Bio humoral tests revealed hyperglycemia, hypercholesterolemia, hepatic cytolysis syndrome, absence of the inflammatory syndrome and myocardial cytolysis. Immunological assessment revealed the presence of the rheumatoid factor and elevated level of anti-cyclic citrullinated peptide antibody (250 IU). Urine test revealed proteinuria and chest X-ray the absence of progressive pleuropulmonary lesions, rectilinear left mid aortic arch, aortic knob calcification, right-hand side basal accentuated pulmonary sketch (fig. 3). The abdominal and pelvic ultrasound imaging confirmed the hepatic steatosis and pancreatic lipomatosis and did not describe other changes. The echocardiogram revealed ischemic heart disease with delayed relaxation type diastolic dysfunction and incipient degenerative aortic valve changes, ejection fraction = 52%, progressing on the background of a chronic immune-inflammatory status, to which a complicated diabetes mellitus is added.

Fig. 1. Third degree obesity

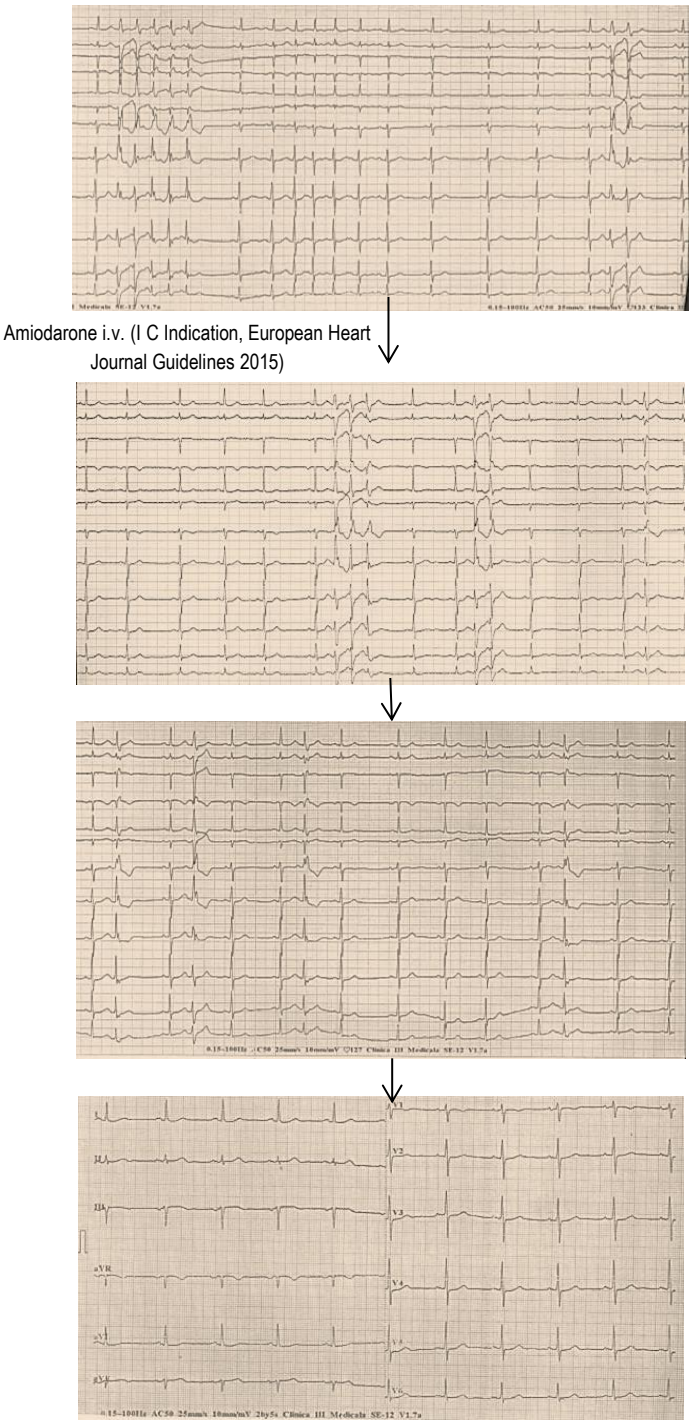

Fig. 2. Electrocardiogram evolution

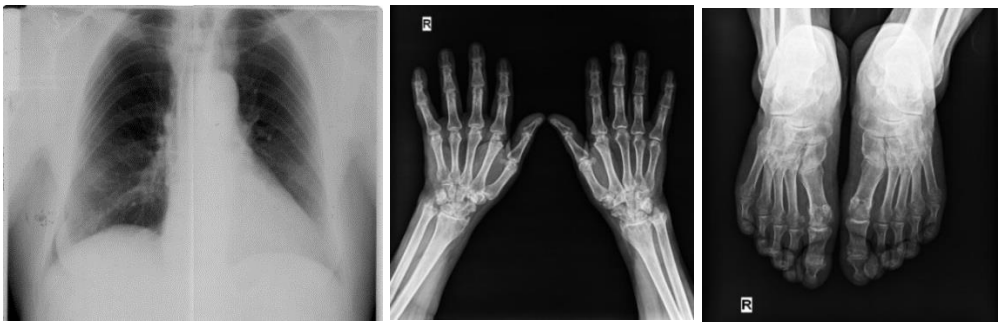

Fig. 3. X-ray aspects

According to the SCORE (Systematic COronary Risk Evaluation) charts which are used to assess the *total death risk* due to cardiovascular disease (coronary and non-coronary) in the last 10 years, the patient was at intermediate risk (3%) (3,4). Following the analysis of Framingham score parameters, which estimate the *coronary cardiovascular accident risk* in the following 10 years, the patient also showed an intermediate risk (14.5%) (3, 4).

The disease activity scores in collagen disease [DAS28 (Disease Activity Score28) = 3.68; SDAI (Simplified Disease Activity Index) = 14.9; CDAI (Clinical Disease Activity Index) = 14] indicated a moderately active disease with an average functional impact (HAQ (Health Assessment Questionnaire) = 1.75) and EULAR (European League Against Rheumatism) response = 0.51 (5).

The electrocardiographic evolution was slowly favorable under specific treatment, arrhythmia being interpreted within the context of silent myocardial ischemia of rheumatoid polyarthritis and diabetic neuropathy.

The prognosis is poor, not only due to the immediate complications of the associated pathology, but also to the distant complications which progress to locomotor disability, development of opportunistic infections or neoplasia because of the immunocompromised state.

DISCUSSION

We reported the case of an obese patient with diabetes, hypertension and dyslipidemia who associated an autoimmune disease – rheumatoid polyarthritis – (*with higher incidence in women!*), showed no response to DMARDs and anti-TNF (Tumor Necrosis Factor) antibodies, with cardiovascular risk score multiplied (x1.5) by the presence of the systemic disease, and who developed symptomatic episodes of tachycardia with important prognostic consequences.

The cardiovascular and rheumatic diseases can coexist (6, 7). The risk of cardiovascular events in rheumatoid polyarthritis is independent, yet amplified by the presence of traditional risk factors (8, 9). Endothelial dysfunction represents the initial link in the development of vascular complications and can be induced by the oxidative stress generated by hyperglycemia and/or insulin resistance (10, 11). The correct and early risk stratification is essential for guiding the treatment. The therapeutic scheme is guided by patient's comorbidities (12).

In these patients, a careful post-discharge monitoring is necessary. Long-term monitoring must include lifestyle change, correction of risk factors and secondary prevention (13). The early recognition and aggressive therapeutic approach of rheumatic disease will reduce the risk of

cardiovascular disease and improve survival and quality of life (14, 15).

CONCLUSIONS

This case describes a patient with rheumatoid inflammatory disease and high cardiovascular risk. Rheumatoid arthritis and cardiovascular diseases share common pathophysiologic mechanisms, which have as consequence the acceleration of process of the atero-forming process. Cardiovascular risk assessment and adoption of cardiovascular disease prevention strategy are integral part of the management of patients with rheumatoid arthritis. Patients with chronic immunoinflammatory RA require regular cardiac screening (clinical examination, electrocardiogram and, in certain conditions, echocardiography). The cardiovascular affection in connective tissue disease requires a dual treatment: of the underlying disease and of the cardiac affection itself according to the current specific guidelines.

MULTIPLE MYELOMA COMPLICATED WITH TAKOTSUBO CARDIOMIOPATHY: CASE REPORT (Abstract): Multiple myeloma (MM) is characterized by clonal proliferation caused by the expansion of monoclonal plasma cells, in which, due to immunoglobulin deposition (M protein/amyloid), renal dysfunction or another organ involvement like cardiac amyloidosis can be periodically encountered. We present the clinical case of a 61-year-old man admitted to our clinic with acute low back pain in the lumbar region. One month earlier, the patient was diagnosed with Takotsubo cardiomyopathy. The lumbosacral spine x-ray showed lumbar vertebral compression fractures and skull x-ray revealed various well-circumscribed lytic bone lesions. The typical M-peak (M band of IgG-kappa monoclonal gammopathy was found) was indicated by serum immunofixation. **Keywords:** TAKOTSUBO SYNDROME, MYOCARDIAL INFARCTION, MULTIPLE MYELOMA, CARDIAC AMYLOIDOSIS, CHEMOTHERAPY.

Multiple myeloma (MM), also known as plasma cell myeloma, is a cancer of plasma cells which was historically defined by end-organ damage, especially hypercalcemia, renal failure, anemia, and bone lesions (CRAB features) that can be associated with the neoplastic process (1). The following three new criteria are used in the diagnosis of MM: greater than 60% clonal plasma cells on bone marrow biopsy, serum free light chain (sFLC) ratio of > 1 (the involved sFLC must be > 100 mg/l), and more than one unequivocal focal lesion on cutting-edge imaging (low dose whole body computed tomography, magnetic resonance imaging, or 18-F-fluorodeoxyglucose-positron emission tomography) (2). Takotsubo cardiomyopathy, also known as "broken heart syndrome", is a transient cardiac syndrome that involves left apical akinesis without obstructive atherosclerotic coronary artery disease. It is believed that this syndrome is triggered by an episode of emotional stress; it frequently occurs in female patients, 12% of patients with an uncertain diagnosis of acute coronary syndromes undergoing cardiac catheterization. Currently, few data in the literature advocate that multiple myeloma can be complicated with Takotsubo cardiomyopathy before the

initiation of chemotherapy (3-11).

CASE REPORT

A 61-year-old man was admitted to University Hospital in Amman, Jordan, with low back pain which lasted for about four weeks. One month earlier, the patient had been admitted to another hospital where he was diagnosed with Broken Heart Disease (Takotsubo cardiomyopathy) and hyperchromic macrocytic anemia. He had been smoking for 40 years-one packet a day-but he did not consume alcohol. He had positive family history of cardiovascular diseases (CVD) but no personal history of other CVD or cardiometabolic syndrome.

At admission, the physical examination showed normal weight (BMI of 24 kg/m²), resting blood pressure (BP) of 120/70 mmHg and heart rate of 85 beats per minute; his respiratory rate was 18 breaths/min, and he was afebrile.

Blood test results showed hyperchromic macrocytic anemia (RBCs = $2.73*10^6/mm^3$, Hb = 11.2 gm/dL, MCV = 122.3 fl, MCH = 40.8 pg). Erythrocyte sedimentation rate, a non-specific indicator of inflammation (normal range for men < 50 years: 0-15 mm/hour) was highly increased (136 mm/h). As to the lipid profile, an important cardiovascular risk factor, the levels of all components: Triglycerides, Total Cholesterol, LDL-Cholesterol, and HDL-Cholesterol were within normal range. However, total protein level was too high = 9.5 g/dL, globulin = 6.4 g/dL and albumin level was too low = 3.1 g/dL. The fasting blood sugar (FBS) and glycated hemoglobin (HbA1c) presented a satisfying short-term and long-term control of blood sugar levels. The renal function, which is evaluated by creatinine and urea levels, was normal, and so were the liver function and the hydro-electrolytic balance. At admission the biological markers of myocardial necrosis-CPK, CK-MB and Troponin T were within normal range. Serum immunofixation showed the typical M-peak (M band of IgG-Kappa monoclonal gammopathy was detected), FLC Kappa = 1500 mg/dL, FLC Lambda = 12.2 mg/dL, and Kappa/Lambda ratio = 122.9. The calcium level was normal. The liver enzyme levels and kidney function were normal, too.

The patient underwent resting electrocardiography (ECG) which showed ST elevation in anterior precordial leads (V1-V5). Fully developed Pardee's waves were seen in precordial leads V2-V3-V4-V5. Sinus tachycardia was about 90 beats per minute; however, the heart rhythm was regular. The normal electrical heart axis (QRS axis) was preserved. Consequently, the patient displayed only electrical signs of lesion and necrosis, specific for supra acute myocardial infarction; however, there were no disturbances of electrical function (fig. 1).

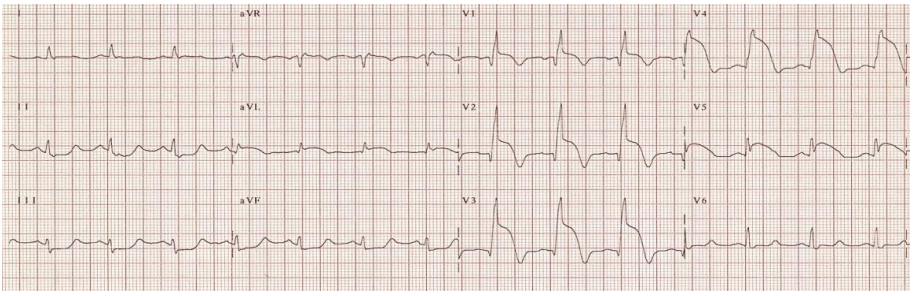

Fig. 1. Electrocardiogram at rest revealed STEMI

The patient underwent chest radiography which showed cardiomegaly with a cardiothoracic ratio of 69.3% and bilateral pulmonary congestion (fig. 2).

The 2D transthoracic Doppler echocardiography demonstrated apical akinesis of the anterior wall. Coronarography showed normal left main artery (LM), left circumflex coronary artery (LCX) and anteroapical akinesis of the left ventricle wall (fig. 3).

Disseminated multiple myeloma has two common radiological appearances, although it should be noted that initially radiographs may be normal despite the presence of symptoms. The two main diffuse patterns are: numerous, well-circumscribed lytic bone lesions (more common), and punched out lucencies, raindrop skull, endosteal scalloping (fig. 4).

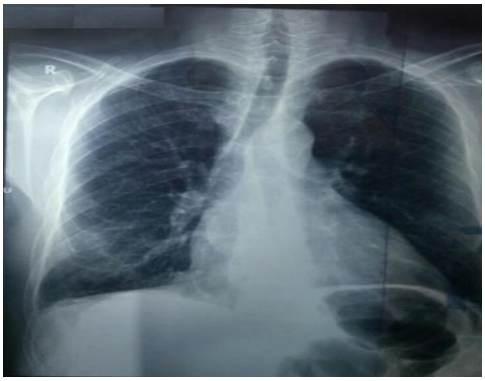

Fig. 2. Chest X-Ray- cardiomegaly with a cardiothoracic ratio of 69.3% and bilateral pulmonary congestion

Fig. 3. Coronarography with normal LM, LCX, LAD and anteroapical akinesis of LV

Fig. 4. Skull x-ray with numerous, well-circumscribed, lytic bone lesions and punched out lucencies

DISCUSSION

Multiple myeloma (MM), also known as myelomatosis, is a rare type of hematological malignancy which accounts for approximately 10% of all hematological malignancies. Osteolytic bone destruction, anemia, recurrent infections and renal impairment are caused by the neoplastic proliferation which is defined as an uncontrolled reproduction of plasma cells in the bone marrow (12).

The diagnostic criteria for MM were updated in 2014 by the International Myeloma Working Group (IMWG) to add specific biomarkers which can be used to make the diagnosis of the disease in patients who did not present CRAB features. Moreover, MM bone disease can be diagnosed by using cutting-edge imaging methods such as computed tomography (CT) and positron emission tomography-CT (PET-CT) Bone pain and bone fractures, anemia, increased susceptibility to infections, hypercalcemia, neurological manifestations, hyper viscosity syndrome, renal failure and progressive osteolytic vertebral fractures are among the most frequently encountered characteristics of MM (13-14).

Approximately 15-20% of the patients suffering from MM secrete monoclonal light chains only, without the expression of the normal immunoglobulin heavy chain, and this constitutes light-chain multiple myeloma. “CRAB” is the abbreviation for high calcium, abnormal kidney function, anemia, and bone lesions. All initial treatments are started when myeloma is symptomatic. MGUS and smoldering myeloma should be carefully followed-up. Bence Jones proteinuria is a disorder characterized by the excretion of monoclonal light-chain protein. MM, which is usually confined to the bone marrow, sometimes infiltrates into other tissues; this phenomenon is known as extramedullary plasmacytoma (EMP). MM is defined as the monoclonal proliferation of bone marrow plasma cells producing multiple bone lesions and overproduction of a monoclonal protein (M-protein) that could amass in tissues (amyloidosis) (15).

In our case the serum immunofixation showed the typical M-peak (M band of IgG-Kappa monoclonal gammopathy was detected) that is specific for the diagnosis of MM.

Takotsubo cardiomyopathy (TCM) is a transient cardiac syndrome that involves the left ventricular (LV) apex akinesis and mimics acute coronary syndrome; this condition is triggered by emotional or physical stress and usually resolves completely (16).

Even though TCM is usually reversible, it can be associated with significant morbidity, such as cardiac arrhythmia. The repolarization abnormalities characteristic to TCM can be associated with characteristic T-wave anomalies and QT prolongation that place patients at increased risk for ventricular arrhythmia, as well as for torsade de pointes. Life threatening arrhythmias such as VT and SCA are prevailing among men, while TTC has been agreed upon to be a disease mainly of females.

TTC may lead to severe heart failure and hemodynamic instability, even if most patients with Takotsubo cardiomyopathy (TTC) have benign clinical course and prognosis. TTC mimics the clinical characteristics of acute anterior wall myocardial infarction (AMI). Generally, clinicians often have difficulties in making the diagnosis whenever cardiac catheterization and angiography are contraindicated or causes adverse effects. In addition, differential diagnosis is also crucial since electrocardiogram findings in patients with Takotsubo

cardiomyopathy and acute coronary syndrome are similar, consisting among others in ST-segment elevation, T-wave inversion, QT-prolongation. Normally, apical involvement with hypercontraction of basal left ventricle (apical type) is prevalent; however, abnormal types affecting basal, mid-ventricular, and right ventricular myocardium have been depicted as well. Patients suffering from acute coronary syndrome die while hospitalized and this is usually caused by hidden conditions (17).

CONCLUSIONS

This case underlines the importance of suspecting a TTC in all patients with myocardial infarction and normal coronarography, mainly if they do not have any cardiovascular disease or symptom at the onset of a major cardiovascular event.

This disease should be suspected more frequently in all patients even though it is rarer in male patients especially if they develop myocardial infarction in the absence of any cardiovascular disease.

POLYCYSTIC LUNG DISEASE: CASE REPORT **(**Abstract): Polycystic lung disease is a particular condition characterized by the presence of multiple air spaces, distributed in both lungs, expression of a syndrome covering rare and multisystem diseases. With the exception of centrilobular emphysema, diseases like lymphangio-leiomyomatosis, Langerhans cell histiocytosis, or lymphoid interstitial pneumonia are rare condition. Clinical, tomographic and histopathologic criteria could be used for the differential diagnosis. We report the case of polycystic lung disease in a 64-year-old male non-smoking firefighter who presented an associated chronic hepatitis C virus infection. Using high-resolution computed tomography, we describe the distribution, size and shape of pulmonary cysts, compatible with centrilobular emphysema. The associated lesions consisted in cystic bronchiectasis and non-significant interstitial linear fibrosis. Based on a literature review, we outline clinical and computed tomography appearances of other causes of polycystic lung disease. **Keywords**: POLYCYSTIC LUNG DISEASE, CENTRILOBULAR EMPHYSEMA, LUNG CYST, COMPUTED TOMOGRAPHY.

Polycystic lung disease (PLD) has an estimated incidence ranging from 3,4 to 7,8 per 1,000,000 population (1, 2). The condition is characterized by the presence of multiple cystic air spaces, usually distributed in both lungs. The cystic lesions should first be differentiated from pulmonary cavities depending on the aspect of the cyst wall, which usually is regular and thinner than 2-3 mm (1-3). The mechanisms leading to cyst formation could be different, depending of the main pathological process at the origin of the syndrome. Except for some types of centrilobular emphysema (CLE), PLD includes rare diseases such as lymphangio-leiomyomatosis, Langerhans cell histiocytosis, lymphoid interstitial pneumonia, pulmonary metastases, Birt Hogg Dubé syndrome and other diseases (1-4). Occasionally, the cysts could contain a small amount of fluid.

High-resolution computed tomography was used to distinguish the characteristics of the pulmonary lesions present in PLD. Per this method, CLE, one of the most frequent types of pulmonary emphysema, was describe as a form of PLD and an important component of the chronic obstructive pulmonary disease (COPD). Less frequent types are represented by pan lobular

and paraseptal emphysema (5). Generally, pulmonary emphysema was associated with an abnormal inflammatory response induced in lung tissue, related to chronic exposure to cigarette smoke and other noxious particles and gases (5).

This paper describes and discusses a case of PLD diagnosed in a 64-year-old nonsmoking firefighter. Clinical and functional data were integrated with high-resolution computed tomography, which describes the distribution, size and shape of pulmonary cysts, compatible with CLE. The associated lesions consisted in cystic bronchiectasis and non-significant interstitial linear fibrosis.

CASE REPORT

A 64-year-old man presented to the hospital because a 2-year history of intermittent episodes of cough with sputum production associated with NYHA class II exertional dyspnea. The family history revealed that the patient had one sister with essential hypertension and type 2 diabetes mellitus and one brother with gastric ulcer. Patient significant medical history consisted of one episode of pneumonia at the age of 30 and other subsequent lung lesions (PLD at the age of 47 years and non-cystic fibrosis bronchiectasis at the age of 60). Bronchiectasis was confirmed by bronchoscopy, and sputum analysis at that time revealed overgrowth of Enterobacter Cloacae and Pseudomonas Aeruginosa. A diagnosis of chronic C hepatitis was documented when the patient was 57-year-old and the immediately initiated antiviral treatment was suspended after 7 months due to the absence of a sustained virological response. The patient received conventional hepatoprotective treatment. He was a nonsmoker but used to be a firefighter and he related chronic respiratory exposure to a polluted environment.

On physical examination, he was found to be overweight (body mass index 28.3 kg/m^2, abdominal circumference 97 cm), afebrile, with acral cyanosis and hand clubbing. The patient had an increased anterior posterior diameter of the chest, prolonged expiratory time, inspiratory crackles and ronchi at the lung bases. Heart auscultation revealed an accentuated pulmonic component of the second heart sound, suggesting pulmonary hypertension. Otherwise, the cardiovascular examination was less significant, without signs of right heart failure. On admission, heart rate was 72 bpm, regular rhythm, and blood pressure was 130/80 mmHg.

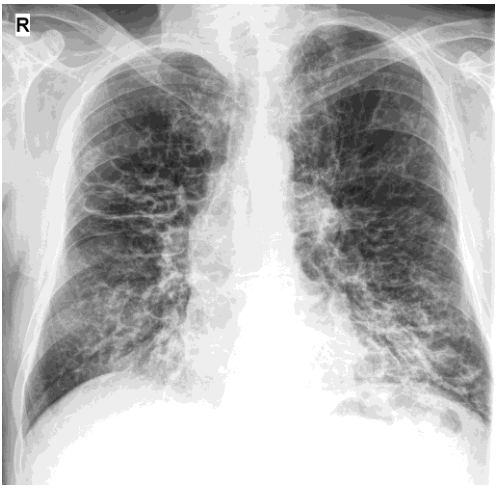

Fig. 1. Poster anterior chest X-ray showing multiple cysts associated with fibrosis and bronchiectasis in both lungs.

Laboratory findings were within normal ranges, excepting for a decrease in HDL-cholesterol (37 mg/dl). Chest X-ray showed bilateral basal emphysema associated with appearance of fibrosis (linear densities) and bronchiectasis. Both upper pulmonary lobes presented multiple rounded and confluent

transparencies, giving the appearance of PLD (fig. 1). Further assessment consisted in a thoracic computed tomography which showed a type of change compatible with PLD (fig. 2, 3); multiple rounded transparencies were present in both lungs, most commonly found it in right upper and left inferior lobe, all with very thin wall and of various sizes up to 38/30 mm, some with minimal fluid content. Other dilations, far smaller, present in the same lung field, were the expression of the associated cystic bronchiectasis. Some inflammatory, small size lymph node enlargements were present in both hilar regions of the lungs. Pulmonary function tests demonstrated a combined defect, with the predominance of airflow obstruction (flow expiratory volume – FEV_1 was 1.23 L, 38,8% of predicted, forced vital capacity – FVC 1.91 L, 46,9% of predicted and FEV_1/FVC% ratio was 85,3%). Pulse oximetry value was normal. Electrocardiogram showed sinus rhythm at 72 beats/min and reduced amplitude of the QRS waves in the extremity leads. Using echocardiography, we noticed the enlargement of the right chambers cavities, compared with the left ones and the right ventricle systolic pressure was estimated at 40 mmHg. The patient received long-term tiotropium inhaler 18 μg/day in combination with mucolytic agents and antibiotics during acute episodes.

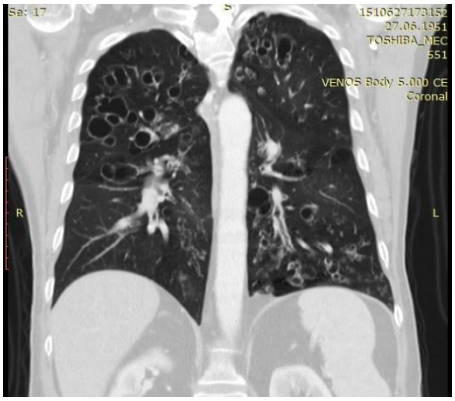

Fig. 2. CT of the lungs (coronal view) – multiple thin wall cysts, more numerous in right upper and left inferior lobes.

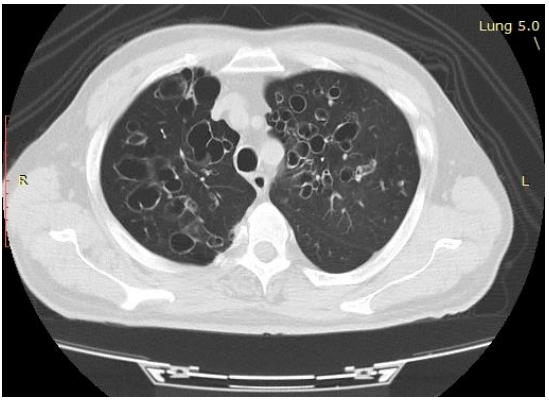

Fig. 3. CT of the lungs (axial view) – multiple thin wall cysts, larger in the right lung.

DISCUSSION

PLD can be encountered in the adult population clinically asymptomatic or accompanied by dyspnea, often suspected after chest radiological examination and confirmed by high-resolution computed tomography (3,4). The patient develops a clinical and radiological syndrome, which is due to a multisystem, but rare disease. The exception is CLE, more frequently encountered in smokers and patients exposed to other noxious particles (3, 4). In our case, chest X-ray showed multiple rounded and confluent transparencies and computed tomography confirmed the presence of disseminated pulmonary cysts. Based on computed-tomography studies, a lung cyst is defined as a round parenchymal area of low attenuation, with a well-defined wall thinner than 2-3 mm, contain-

ing air, but rarely a solid material or a small amount of liquid. In contrast, a cavitary lesion will develop mainly in an area of pulmonary consolidation, mass or nodule and the cavity wall will be thicker than 4 mm (3,6,7). For the final diagnosis, the clinical characteristics should be correlated with the shape and distribution of the cysts on the computed tomography and, in many cases, with histopathology features. The main diseases that may cause pulmonary cysts are presented in table I (3, 7).

TABLE I

The principal causes of PLD (3, 7)

Pathologic condition	Clinical findings / Appearance on computed tomography
Centrilobular emphysema	Clinical history of smoke and dust exposure/ Upper lobe predominance, non-perceptible or thin cyst wall, presence of a centrilobular artery
Langerhans cell histiocytosis	Young patient, cigarette smoker/ Combination of nodules, cavitating nodules and cysts
Lymphangio-leiomyomatosis	Young women with dyspnea, recurrent pneumothoraxes, hemoptysis/ Thin wall rounded cysts, may involve the juxtaphrenic recesses
Lymphoid interstitial pneumonia	Women in 5th decade, associated with collagen vascular disorder or HIV infection/Cysts mixed with ground-glass opacities and nodules
Hypersensitivity pneumonitis	Diffuse granulomatous inflammatory disease caused by exposure to organic and anorganic particles/ Few cysts in 10% of cases
Desquamative interstitial pneumonia	Smoking history/ Ground-glass aspect and small cysts
Metastases (sarcoma, squamous cell cancer, carcinoma of the bladder, melanoma)	Tumoral syndrome/ Different sizes and lower predominance
Neurofibromatosis type I	Café-au-lait spots, neurofibromas, optic nerve glioma, Lisch nodules, skeletal lesions/ Cysts in both upper lobes
Pneumatoceles	Caused by pneumonia (*Pneumococcus* species, *Escherichia coli*, *Klebsiella* species, *Staphylococcus* species, *Pneumocystis jiroveci,* trauma and inhalation of hydrocarbon fluid/Thin wall cysts

Other causes far less commonly mentioned in literature are cystic fibro histiocytic tumor of the lung, tracheal papillomatosis, cystic mesenchymomas, light-chain disease or Birt Hogg Dubé syndrome (pneumothoraxes, renal cell carcinomas, skin fibro-folliculomas) (3).

Our patient had a history of pneumonia at the age of 30 and chronic exposure to noxious gases, he never smoked and there are no arguments supporting the clinical features of a multisystem disease. The

pneumonic episode could have contributed to the progression to polycystic CLE. Computed tomography revealed the characteristics of the cysts and the association with bronchiectasis and mild fibrosis.

Generally, particular cases will require correlation with histopathology findings or a highly specific biomarker, such as an increased serum VEGF- D level in lymphangio-eiomyomatosis (2).

Another particularity of this reported clinical case is represented by the chronic infection with hepatitis C virus, but probably unrelated to the pulmonary findings. The pulmonary disease was relatively stable on chronic treatment and during the 7 months of antiviral treatment the clinical and radiological course was unchanged. Cases of chronic hepatitis C virus infection associated with or complicated by pulmonary diseases (sarcoidosis, pulmonary fibrosis, asthma) (8-10), occasionally due to antiviral therapy, have been reported in the literature (11). However, a study published in 2014 demonstrated that hepatitis C virus infection is not an independent risk factor for COPD (12).

CONCLUSIONS

Our paper presented a particular case of PLD in a male nonsmoking firefighter who associated a chronic infection with hepatitis C virus. The clinical course, stable over years, and the computed tomography findings are highly suggestive of a CLE, one of the main causes of PLD.

THE IMPACT OF SOCIOECONOMIC STATUS AND NUTRITIONAL BIOCHEMICAL MARKERS ON QUALITY OF LIFE OF CHRONIC DIALYSIS PATIENTS (Abstract) **Aim**. This cross-sectional study aimed to determine the relationship between socio-economic status and laboratory values with mental and physical components of QoL (quality of life) in chronic dialysis patients. **Material and methods:** 254 patients were included in the study and divided into two groups: 243 hemodialysis (HD) patients and 11 peritoneal dialysis (PD) patients. QoL was measured by the Short Form 36(SF-36). Scores for all dimensions are expressed on a 0-100 scale. Higher score indicates better health status. Two more questions related to monthly food expenditure and the presence/or lack of family support were added. Laboratory investigations included the following nutritional parameters: serum albumin and creatinine. **Results:** Our study results showed that compared to PD group in HD patients QoL was compromised in all SF-36 subscale except physical functioning, role limitations due to physical functioning and role limitations due to emotional functioning. Also, the presence of supportive family members/ caregivers showed a significant improvement of all QoL scores. HD patients who spend at least 90 euros monthly on groceries/food had higher values of SF-36 items. Better QoL is associated with high pre-dialysis serum creatinine and serum albumin levels. **Conclusions:** Future work should incorporate larger and more balanced sample sizes and patient recruitment from multiple dialysis centers to truly capture the variability in patient characteristics. **Keywords:** HEMODIALYSIS, QUALITY OF LIFE, SF-36, SOCIO-ECONOMIC STATUS.

Chronic illnesses and their treatments, including *End-Stage Renal Disease* (ESRD) and dialysis, have great impact on the functioning and well-being of patients. Dialysis is both life-saving and life-altering, changes a person's lifestyle completely and has great impact on physical, mental, and social well-being (1). The Kidney Disease Quality of Life (KDQoL) instrument was developed for assessing the

quality of life of individuals with kidney disease and on RRT (renal replacement therapy). Short-Form 36 Health Survey (SF-36) consists of eight dimensions, generating a profile of health-related quality of life (HRQoL) (2). In patients with ESRD QoL is influenced by the type of RRT. It is unclear whether hemodialysis (HD) or peritoneal dialysis (PD) is associated with a higher HRQoL (3).

In Romania, data on QoL among chronic dialysis patients is limited. Most studies in dialysis population showed that higher income is positively correlated with role emotional and mental health (4). Low socio-economic status is associated with poor health outcomes (5). In addition to the inherent discomfort caused by the disease and social problems the patient experiences difficulties in fulfilling social, professional, family obligations, up to temporary or permanent work incapacity (6).

None of the currently favored biochemical nutritional markers has been demonstrated to accurately reflect nutritional status in CKD (7). Serum albumin is still being used for research purposes and, in the clinical setting, as a biomarker of nutritional status. Malnutrition is highly prevalent in ESRD patients and is a major contributor to poor quality of life (8).

The objectives of our study were: 1. to evaluate QoL among patients undergoing chronic dialysis therapy; 2. to determine if there is any correlation between socio-economic status and nutritional laboratory data with QoL.

MATERIAL AND METHODS

This cross-sectional study, performed at the B. Braun Hemodialysis Unit, Botosani Romania, included 254 patients meeting the following criteria: 1) on regular dialysis therapy for more than three months; 2) no apparent mental diseases to avoid potential misinterpretation of the questions; 3) 18 years and above, 4) stable condition, meaning no hospital admission at least one month prior data collection. Written informed consent was obtained from all patients before enrollment in the study. 243 HD patients and 11 PD patients completed the SF-36 questionnaire.

Quality of life questionnaire was measured using a RAND Short Form 36-Items Health Survey (version 1.0) which taps eight health concept: 1) Physical Functioning (PF); 2) Role Limitations due to Physical Functioning (RPF); 3) Bodily Pain (BP); 4) General Health Perceptions (GH); 5) Vitality (VT); 6) Social Functioning (SF); 7) Role Limitations due to Emotional Functioning (REF); and 8) Mental Health (MH) (9). Raw scores on each dimension are transformed into a score ranging from 0-100. Higher scores indicate better health. To evaluate socio-economic status, we added to this questionnaire two more questions: 1. Does the patient have any caregivers at home to cook for him/her regularly-following the nutritional recommendations received at the Dialysis Center? 2. Does the patient spend at least 90 Euros per month on food/groceries?

Medical history and laboratory data (serum albumin and creatinine) were obtained from patients medical and dialysis record.

The statistical study was conducted in SPSS 16.0 for Windows. We determined the frequency distributions and we determined the elements of descriptive statistics for the numerical parameters: mean value, mean standard error (MSE), standard deviation (SD), minimum and maximum values. We used the *t* test and the Mann-Whitney nonparametric test (U) for inde-

pendent samples of the comparative study between the groups for numerical variables, having previously checked the hypothesis that variables abide the normal law using the Kolmogorov-Smirnov fitting test. The level of significance $p<0.05$ was considered statistically significant.

RESULTS

Assessing quality of life among the chronic dialysis patients by SF-36 questionnaire revealed significant differences between the two patient groups, except for PF, RPH şi REP; overall global QoL score was significant lower in patients undergoing HD (p=0.013). In PD group SF had the highest score (77.27 ± 12.27) and RPF the lowest score (50.00 ± 27.38). In HD patients, the lowest score was on VT (30.41± 21.71) and GH (35.14 ± 22.79). It is noteworthy that PD patients scored significantly better on VT, MH and SF than HD patients (tab. I). Regarding bodily pain, HD patients scored significantly lower (more pain) than PD patients (p=0.022) (tab. I).

TABLE I

Global and group coefficients of all eight dimensions and relevant laboratory values. For each scale, SF-36 the score ranges from 0-100, with a higher score indicating better QoL

	All patients n=254 mean ±SD	HD group n=243 mean ±SD	DP group n=11 mean ±SD	P

169 (69.54 %) from HD patients declared that at least one family member help them in kitchen and cook for them following dietitian recommendations. In HD patients, the presence of supportive family members/ caregivers was associated with a significant improvement on all scores rating the QoL except MH score. In PD group, there were no relatives to help the respondents (tab. II).

SF-36 subscale abbreviations: PF-Physical functioning; RPF- Role limitation due to physical functioning; REF- Role limitation due to emotional functioning; VT-Vitality; MH-Mental health, SF-Social functioning; BP-Bodily pain; GH-General health perception; HD-hemodialysis; PD- peritoneal dialysis; Caregivers/ family yes- presence of the members' family, no- lack of family; p <0.05 –significant statistic.

114 (46.91%) from HD patients who were spending at least 90 euros monthly on groceries/food had higher values of SF-36 items than the others. Only one patient in PD group used to spend more than 90 euros per month but he showed only sporadic improvement in the SF-36 items (tab. II).

Half of the HD sample had serum albumin levels below the normal range (tab. II). In the presence of low serum albumin levels the most affected scores were RPF and VT (17.82±3.04 and 19.07±1.84, respectively). The lowest decline was found in MH score. Serum creatinine correlates well with all SF-36 scores, meaning that low levels correspond to low QoL. In HD group a significant correlation was identified between low serum creatinine and RPF, PF and REF scores (p=0.000, p=0.000 and p=0.009, respectively). The lowest correlation was found with MH score (p= 0.139).

DISCUSSION

Dialysis care has increased in importance throughout the world because of the growing prevalence of patients receiving RRT, its related morbidity and mortality and high social and financial costs (10). This study aimed at describing HRQoL (Health Related Quality of Life) within the context of dialysis care. Global QoL score was almost 40 % higher in PD patients compared to HD group, perhaps due to the slightly advanced age in HD group, although PD patients had lower food expenditure and lacked support from family members. The small number of PD patients could be considered a limitation of our study. Liem et al. (11) conducted a systematic review on HRQoL of HD an DP patients but did not find statistically significant differences between dialysis modalities. Vacaroiu et al. (12) found that PD was a better option for dialysis in elderly people. However, considering that dialysis treatment is chronic, maybe these statistically significant results need more careful observation regarding changes that occur as the disease progresses.

Among our cohort of patients, we found that economic factors like monthly food expenditure and family support varied in an expected direction showing poverty levels and material disadvantage for this population. Almost all our study patients have low monthly retirement income and healthcare allowance, characterizing a population with low socio-economic status. Also, nearly half of HD patients spent monthly on food at least 90 Euros compared to 10% of the PD group. So, in HD group, the patients who met this criterion presented a statistically significant improvement in all QoL scores. In PD group, only one patient had a monthly food budget of more than 90 euros which was sporadically reflected in improved QoL scores. One theme remains questionable: subjectivity of monthly food spending reported by the patients. Many of them did the shopping together with their family so such an assessment may also be over- or underestimated. Poverty, low income, lack of knowledge and access to information contribute to low QoL (13).

Mingardi et al. (14) in a multi-center study aimed at better understanding the relationship between albumin level and SF-36 scores, classified the patients into four groups from low to high albumin level. The results showed that with increasing serum albumin levels better self-reported HRQoL is registered. It is said that serum creatinine level indicates skeletal muscle mass, although an elevated level before dialysis means having suboptimal dialysis or long time without dialysis. The present study showed that high serum creatinine and albumin levels are associated with better QoL. Low PF and RPF scores, 2 items that indicates physical activities were associated with the lowest serum creatinine levels which can be linked with a possible low muscle mass.

CONCLUSIONS

This study highlights the decline of quality of life in patients with low socio-economic status, especially in the vulnerable subgroups of single and financially deprived patients. In our study the alterations of nutritional biomarkers was associated with low QoL. Prevention of protein-energy malnutrition can improve and maintain a high QoL in chronic dialysis patients. The limitations of the research were: single-center cross-sectional study; because of the small number of patients in PD group statistical estimation could not be obtained.

DIETARY VITAMIN D, CALCIUM, AND MAGNESIUM INTAKE IN TYPE 2 DIABETES PATIENTS (Abstract): **Aim**: To estimate specific nutrient intake in patients with type 2 diabetes. **Material and Methods**: The study was conducted on a group of subjects with type 2 diabetes. The collected data included: anthropometry, lifestyle, blood measurements, and the mean daily nutrient intake assessed by the EPIC food frequency questionnaire. **Results**: The study group included 101 subjects with type 2 diabetes mellitus (DM) with a mean age of 60.6±10 years, of which 45 men (59±10.6 years) and 56 women (62±9.6 years). The average energy intake was 1714.4±713.9 Kcal/day, with a statistically significant gender difference (1877.7±850.9 kcal/day for men, 1583.1±554.9 kcal/day for women, p = 0.039), and the average daily micronutrient intake was 2.44±1.44 μg/day for vitamin D, 724.5±263.2 mg/day for calcium (Ca), 266.7±98 mg/day for magnesium (Mg), which was low compared to dietary recommendations. Calcium intake was correlated with intake of carbohydrates, saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), fiber and energy. Vitamin D intake was correlated only with protein intake (R=0.695), while magnesium intake correlated with intake of fibers, energy, carbohydrates and SFA. **Conclusions**: Our study in patients with type 2 diabetes showed a reduced average intake of calcium, magnesium and vitamin D compared to standard recommendations, requiring an individualized approach. **Keywords**: NUTRIENTS, FOOD FREQUENCY QUESTIONNAIRE, TYPE 2 DIABETES MELLITUS.

The assessment of nutritional intake through food survey consists in collecting information on the amount and type of foods ingested and on calculating nutrient intake based on their composition. Even tough dietary research methods (dietary patterns research) are imperfect and the methodological aspects of analysis have some limitations, they are widely used for nutritional recommendations and food policies (1,2). Food frequency questionnaires (FFQ) are the most commonly used dietary assessment method in epidemiological studies. FFQ are used to characterize dietary exposures and to explore the relationship between diet, risk of illness and/or disease progression. Diabetes is an extremely important medical condition, given its prevalence, negative impact on life expectancy and quality and the extremely high costs involved (3). Medical nutrition therapy has an important role in the prevention and management of type 2 diabetes.

The aim of this study was to assess the

specific nutrient intake in a group of patients with type 2 DM and to compare these with the standard dietary recommendations.

MATERIAL AND METHODS

The study group included 101 adult subjects with type 2 DM who did not take inulin and were scheduled for the regular medical checkup at the diabetes ambulatory unit; patients' mean age was 60.6±10 years, 45 were men (mean age 59±10.6 years) and 56 women (mean age 62±9.6 years). Participants were interviewed face-to-face about lifestyle, area of residence, education, occupation, physical activity, medical history. To assess dietary intake, we used the EPIC FFQ which was validated earlier on a Romanian population (4). The questionnaire consists of 130-items (foods and drinks) divided into 10 major food groups, and subjects were asked to specify the frequency of their consumption during the last year. Portion sizes were evaluated by discussion and demonstration drawings. Data collected via questionnaire were analyzed by FETA-FFQ EPIC Tool for Analysis (5), which converted data on food consumption into nutrient intake. In addition, information regarding diabetes duration and chronic complications were obtained. Weight, height, and waist circumference (WC) were measured and body mass index (BMI) was calculated. Also measured were systolic (SBP) and diastolic blood pressure (DBP). Blood was collected for biological parameter measurement (blood glucose, glycated hemoglobin - HbA1c). Statistical analysis was performed using SPSS v17. The significance of differences between the mean values of the studied variables was checked using the Mann-Whitney test, ANOVA and chi-square test for independent samples, considering statistically significant those differences with a level of significance of $p<0.05$.

RESULTS

Of the analyzed parameters, compared by gender, a statistically significant difference was found for weight, height and BMI. Regarding the presence of specific chronic complications of diabetes, 5.1% of the study subjects had retinopathy, 22.2% - neuropathy, 1% - peripheral arterial disease (PAD), and 76% hypertension, with gender differences, but lacking statistical significance (tab. I).

The average energy intake was 1714.4±713.9 Kcal/day, with a statistically significant difference between genders (1877.7±850.9 kcal/day for men, 1583.1±554.9 kcal/day for women, $p=0.039$). Otherwise, there were no statistically significant differences between men and women in macro- and micronutrients intake (tab. II). The percentage of caloric macronutrients was balanced according to guidelines, as follows: carbohydrates 49.02% (48.8% for men, 49.2% for women), proteins 19.2% (19.1% for men and 19.3% for women) and lipids 31.88% (32.1% for men, 31.5% for women). Total energy intake correlated with the intake of carbohydrates, proteins and lipids. These percentages are consistent with dietary recommendations (6).

Only 13.9% of subjects ingested the recommended daily dose of calcium (1200 mg/day): 13.3% of men and 14.3% of women ($p>0.05$). As to magnesium, 25.7% of subjects ingested the recommended daily dose (22.2% of men and 28.6% of women, $p>0.05$) and 5% (4.4% of men and 5.4% of women, $p> 0.05$) ingested the recommended daily dose of vitamin D. No statistically significant correlation was found between the intake of vitamin D, calcium, and magnesium and age, BMI, duration of diabetes

and HbA1c. However, there was a statistically significant inverse correlation between vitamin D intake and fasting blood glucose (R = -0.272, p = 0.017).

* MUFA=monounsaturated fatty acids, PUFA= polyunsaturated fatty acids, SFA=saturated fatty acids

The intake of vitamin D, calcium, and magnesium was positively statistically significantly correlated with all macronutrients analyzed (energy, carbohydrates, fibers, proteins, and lipids). Thus, we conducted a multivariate linear regression to find out which of the macronutrients and energy significantly influence the intake of micronutrients. Regarding calcium intake, it depended on carbohydrate, saturated fat, monounsaturated fat, fiber and energy intake, in that order, explaining 83.5% of the total calcium intake. Vitamin D intake remained significantly influenced only by protein intake (R = 0.695). Magnesium intake was influenced by the intake of fiber, energy, carbohydrates and saturated fat in a proportion of 90%. Subsequently, ROC curve analysis highlighted that for the diabetics in our study an intake of 259.03 g carbohydrates would suffice to provide the recommended daily dose of calcium. This would mean that this population should increase carbohydrate intake to 60% of daily energy intake, or increase caloric intake, in order to reach the recommended calcium intake.

DISCUSSION

A norm caloric balanced diet usually provides all the nutrients, and supplements are required only in at risk sub-populations or when deficiencies are demonstrated (6). Some authors (7) have shown that a high-carb low-fat diet has been associated with a higher risk of developing type 2 diabetes. Foods with a high glycemic index together with an increased proportion of lipids, were also found to increase the risk of diabetes (8). Schulze *et al*. (9) concluded in the EPIC-Potsdam study that replacing carbohydrates with protein and PUFA was associated with a reduced risk of type 2 diabetes. A systematic review (10) based on prospective randomized controlled trials showed that nutrients, other than carbohydrates, affected glycemic control and explained the mechanisms by which these nutrients influenced insulin secretion and action. Magnesium supplements decrease the risk of complications in people with diabetes, improving insulin secretion and insulin signaling (11). The results of a large prospective study suggested the beneficial role of both vitamin D and calcium intake in reducing the risk of type 2 diabetes (12). Food supplementation is preferred both in preventing and treating diabetes (13).

When analyzing the questionnaire-derived data we found that most of our subjects, both male and female, had a lower average daily intake of micronutrients (vitamin D, calcium, and magnesium) compared to standard recommendations (1200 mg Ca, 5 μg vitamin D and 320 mg Mg for women and 420 mg men), but without statistically significant gender differences. These nutritional deficiencies are however consistent with the statistical data on the Romanian population, namely a low intake of fruits and vegetables, fish and dairy products (14). It is also suggested that low vitamin D levels are an independent risk factor in diseases prognosis (15). Interaction between vitamin D and calcium is known and treatment of these deficiencies is done together. The consumption of foods rich in calcium is safe in terms of cardiovascular risk, use of calcium supplements should be reserved for patients who truly need supplementation (16). Magnesium depletion is a common problem in patients with DM and it affects glycemic status and progress of complications (17). Magnesium is a cofactor for vitamin D biosynthesis, transport, and activation. The consequences of suboptimal magnesium status in diabetic populations eating

modern diets are important because of the interactions of magnesium with the nutrients calcium and vitamin D. All three must be supplemented simultaneously (18).

Given that the proportion of macronutrients is according to guidelines, it means that increasing the food amount of vitamin D, calcium and magnesium, could be achieved only by increasing the calories. Therefore, one emerging conclusion is that each case should be addressed individually. Correcting these deficiencies would improve glycemic control and reduce the risk of complications.

CONCLUSIONS

In our group of diabetics, calcium intake was insufficient and depended on the intake of carbohydrates, saturated fat, monounsaturated fat, fiber and energy. Vitamin D intake was low and depended only on protein intake. Magnesium intake was low and was also influenced by the intake of fiber, energy, carbohydrates and saturated fat. Evaluating the sources of vitamin D, calcium and magnesium for each patient could lead to correct recommendations of either dietary adjustments or use of supplements.

CORRELATION OF MONOCYTE/HDL CHOLESTEROL RATIO WITH SYNTAX SCORES IN PATIENTS WITH STABLE CORONARY ARTERY DISEASE

Monocytes play a pivotal role in the inflammatory cascade, being the first inflammatory cell type that infiltrates early atherosclerotic plaques. The study authors investigated the role of monocyte/HDL cholesterol ratio in predicting the severity and complexity of coronary lesions quantified by the SYNTAX score in patients with stable coronary artery disease undergoing coronary angiography. The study was conducted over a 3-year period, 428 patients underwent coronary angiography being investigated. All patients were clinically stable. They were excluded from the study patients with an acute coronary syndrome, malignancy, acute or chronic inflammatory diseases of the liver, kidney or other organ and patients who had previously undergone percutaneous coronary intervention and coronary artery bypass grafting. Transthoracic echocardiography was performed in all patients, and left ventricular ejection fraction (LVEF) was calculated using Simpson's method. Severe coronary artery disease was defined as having a SYNTAX score ≥ 23. The patients were divided into two groups: those with low SYNTAX score (< 23) and those with high SYNTAX score (≥23). Of the 428 patients included in the study, 161 patients had a SYNTAX score ≥ 23. The treatment with ACE inhibitors or angiotensin receptor blockers, beta blockers, statins and acetyl salicylic acid were similar in low and high SYNTAX score groups. Also, age, gender, hypertension, smoking status, instance of diabetes mellitus, hyperlipidemia, and positive family history were similar between groups. In the patients with SYNTAX score ≥ 23, multivessel disease showed a higher incidence. Monocyte/HDL cholesterol ratio and C-reactive protein (CRP) were significantly higher in patients with high SYNTAX score ($p<0,001$). As well, WBC count, total bilirubin, LVEF and HDL level were significantly correlated with SYNTAX score in stable coronary artery disease. Left ventricular ejection fraction was lower in the group with high monocyte/HDL cholesterol ratio and high SYNTAX scores. The cutoff value of monocyte/HDL cholesterol ratio that predicted a high SYNTAX score was 24, with a sensitivity of 66% and a specificity of 65,1%. In conclusion, monocyte/HDL cholesterol ratio is significantly associated with SYNTAX score. Monocyte/HDL cholesterol ratio can be used as a prognostic marker in patients with stable coronary artery disease, because it is an quickly accessible and inexpensive test (H. Kundi, E. Kiziltunc, M. Cetin, H. Cicekcioglu, Z. G. Cetin, G. Cicek, E. Ornek. Association of monocyte/HDL-C ratio with SYNTAX scores in patients with stable coronary artery disease. *Herz* 2016; 41(6): 523–529).

EXTRADIGESTIVE MANIFESTATIONS OF GASTROESOPHAGEAL REFLUX DISEASE: DEMOGRAPHIC, CLINICAL, BIOLOGICAL AND ENDOSCOPIC FEATURES (Abstract): Gastroesophageal reflux disease (GERD) with extradigestive manifestations is a disorder increasingly recognized both by gastroenterologists, pneumologists, otolaryngologists and cardiologists. **Aim:** To evaluate the demographical, clinical, biological and endoscopic features of the patients with gastroesophageal reflux disease and extradigestive manifestations (chronic laryngitis, asthma, pseudoangina). **Material and methods:** Prospective case-control study, including 137 patients selected from patients referred to the Iasi Institute of Gastroenterology and Hepatology between July 2014 - September 2015. In the presence of typical GERD symptoms (heartburn or regurgitation), the patients were assessed by upper digestive endoscopy for the detection or exclusion of esophagitis. Despite the absence of esophageal lesions, the patients were further assessed by impedance-pHmetry. **Results:** Depending on the dominant extradigestive manifestation, the patients were assigned into 3 groups: 94 chronic laryngitis patients, 24 asthma patients and 19 pseudoangina patients. Females were more frequent among pseudoangina patients (68.4%). Mean age of the male patients with dysphonia or asthma was lower (p=0.002), the majority (78.1%) living in urban areas. Obesity was predominant in pseudoangina group (52.6%), as compared to dysphonia group (16%) the differences being statistically significant (p=0.002). A share of 57.9% of pseudoangina patients were dyslipidemic, in contrast to dysphonia (24.5%) or asthma group (37.5%) (p=0.013). Esophagitis was also more frequent at pseudoangina group (84.2%), but with no significant statistical difference between the study groups (79.8% and 75%, respectively) (p=0.115). It seems that *Helicobacter pylori* infection tends to be protective in patients with GERD and pseudoangina (RR=0.61), but it can not be extrapolated to the general population (p=0.459). **Conclusion:** GERD with extradigestive manifestations is a prevalent and heterogeneous disease. There are demographic, clinical, biological and endoscopic differences between patiens with extradigestive GERD. **Keywords:** GASTROESOPHAGEAL REFLUX DISEASE, EXTRADIGESTIVE MANIFESTATIONS.

Gastroesophageal reflux disease (GERD) with extradigestive manifestations is a topic debated in literature in the last decades. It became an important diagnostic issue for both gastroenterologists and specialists in other medical fields, like otolar-

yngology, cardiology, pneumology and dentistry, as demonstrated by the increasing number of patients suspected of GERD which are referred to gastroenterologists from these services. Apparently a banal disease, GERD has a significant morbidity, consuming human and material resources and burdening health system budget. So far, in Romanian literature there are limited data on extradigestive GERD.

The aim of this study was to evaluate extradigestive GERD patients in terms of demographic, clinical, biological and endoscopical features.

MATERIAL AND METHODS

A prospective case-control study including 137 patients referred to the Iasi Institute of Gastroenterology and Hepatology Iasi from otolaryngology, cardiology and pneumology services in the interval July 2014-September 2015 was performed. Included in the study were adult patients previously diagnosed with asthma, non-cardiac chest pain or chronic laryngitis in whom GERD was suspected. Written informed consent for the participation in the study was obtained. Excluded from the study were the patients with prior gastric or esophageal surgery, malignant tumors, esophageal motility disorders (achalasia, scleroderma, myopathies), alarm signs (hematemesis, jaundice, unexplained weight loss), psychiatric disorders, pregnant women, peptic ulcer, active tuberculosis or other acute lower respiratory tract infections, unstable arrhythmias or myocardial infarction in the last 6 months.

Demographic data, personal history of diseases and smoking and anamnesis were recorded in individual files. All patients were tested for *Helicobacter pylori* antibodies by ELISA. As it is known that dyslipidemia and obesity are risk factors for GERD, the cholesterol and triglycerides serum levels were analyzed and body mass index (BMI) was calculated in all patients. Obesity was considered if BMI was greater than 30 kg/m^2.

Depending on the presence/absence of typical symptomatology (heartburn or regurgitation), the patients were differently investigated in order to diagnose or exclude GERD. The patients presenting typical manifestations underwent a therapeutic test with double-dose PPI (Pantoprazole 40 mg BID), while the patients not presenting the classical symptoms were assessed by upper digestive endoscopy (UDE) for the detection of the lesions of esophagitis or hiatus hernia. In some cases, biopsies were taken and submitted to anatomo-pathological exam for diagnosing or excluding a Barrett's esophagus. Patients without esophageal lesions were further assessed by impedance-pH metry in order to make a certain diagnosis of GERD.

The data were statistically analyzed using *SPSS 18.0.* The used parametric tests were: student's t- test for comparing the means, χ^2-test for comparing frequency distribution and Pearson's test correlation coefficient. A p value < 0.05 was regarded as statistically significant.

RESULTS

According to the predominant extradigestive manifestation, the patients were assigned into 3 groups: group I included 94 patients with chronic laryngitis, group II-24 patients with asthma and group III-19 patients with non-cardiac chest pain.

Demographic features. Both non-cardiac chest pain group and chronic laryngitis group showed a slightly tendency towards females (68.4% and 52.1%, respectively), while asthma patients were more likely to be men (58.3%), the majority (78.1%) living in urban areas. The study patients were homogenous in terms of gender (p=0.218): 47.4% were males and 52.6% were females (fig. 1).

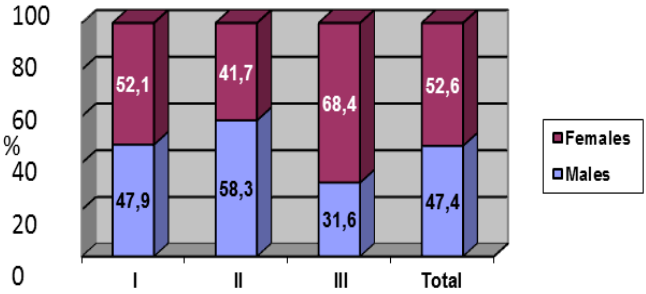

Fig. 1. Gender distribution

The age of reflux laryngitis patients ranged from 20 to 83 years, with a mean of 50.33±15.10 years and a median of 50 years. In the asthma group the mean age was slightly lower than in group I (50.25 ±14.14 years) and the median was also 50 years. The age of non-cardiac chest pain patients ranged between 44 and 74 years, with a median of 59 years and a mean age of 58.84±8.33 years, which is significant higher compared to the other two groups (p=0.05) (tab. I). The age > 50 years induced an estimated risk of GERD four times higher in the pseudoangina group (p=0.012).

Mean age was lower in males presenting asthma and laryngitis (p=0.002).

Of the 137 patients enrolled, 1 was under 20 (0.7%) and 3 (2.2%) were over 80 years of age. In group I the pick frequency was between 40-49 years (26.6%), in group II-between 50-59 years (33.3%) and in group III-between 60-69 years (47.4%) (p=0.026) (fig. 2).

TABLE I.

Descriptive statistical indicators of age (years) by study groups

Study group (Lots)	N	Mean	Standard deviation	Std. error	Confidence interval		Min	Max	p F_{ANOVA} test
					- 95%CI	+95%CI			
I	94	50.33	15.10	1.56	47.24	53.42	20	83	0.050
II	24	50.25	14.14	2.89	44.28	56.22	18	77	
III	19	58.84	8.33	1.91	54.83	62.86	44	74	
Total	137	51.50	14.41	1.23	49.06	53.93	18	83	

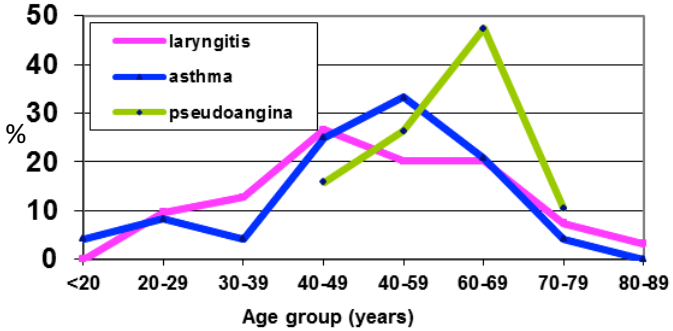

Fig. 2. Percent distribution of events by age

Clinical features. Typical reflux symptoms were more frequent in asthma subjects (54.2%), but there were no significant statistical differences between this group and laryngitis (39.4%) and non-cardiac chest pain patients (36.8%) (p=0.384) (fig. 3).

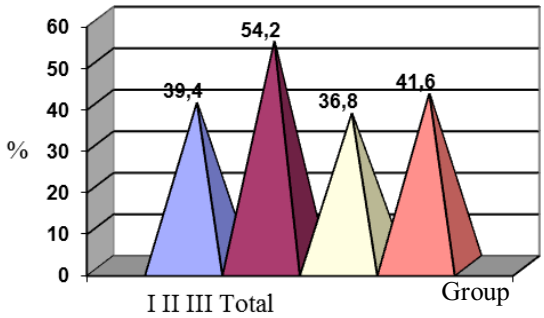

Fig. 3. Distribution of typical symptoms by study groups

The highest frequency of obese patients was found in the pseudoangina group (52.6%) and the lower in the laryngitis group (16%), with significant statistical differences (p=0.002); the overall percentage of obese people was 23.4%.

According to smoking status, the patients' distribution by study groups was homogenous. Although the group with pseudoangina recorded the lowest rate of smoking patients (5.3%), there were no statistical differences between reflux laryngitis (18.1%) or GERD-related asthma patients (25%) (p=0.234).

Biological features. Dyslipidemia was found in 57.9% of patients presenting non-cardiac chest pain, which is a significantly higher frequency in comparison with the other two groups (24.5% for laryngitis and 37.5% for asthma) (p=0.013).

Helicobacter pylori infection was identified in 52.6% of all GERD patients, without any significant statistically differences between study groups; the fewest cases of infection with *Helicobacter pylori* were identified in the pseudoangina group (p=0.619).

Endoscopic features. The percentage of patients presenting esophagitis on UDE examination was found to be higher in the group with non-cardiac chest pain (84.2%) compared to the other two groups (79.8%, 75% respectively) (p=0.115). Statistical analysis showed Barrett's esophagus in only 6.6% of GERD patients, but with no significant differences between the study groups (p=0.457). Hiatus hernia occured in 63.2% of pseudoangina patients and in only 36.2% and 41.7% of patients with laryngitis and asthma, respectively (p=0.094).

DISCUSSION

Our study is one of the few studies on extradigestive GERD conducted in our country. It is known that GERD with or without extradigestive manifestations is found in approximately equal proportions in both genders, with a slight tendency towards males (1, 2). In our study there was a gender homogeneity of the study groups, with a slightly higher frequency of women in the group with chest pain of non-cardiac cause.

GERD can occur at any age, but it is most commonly diagnosed after 40 years

(3, 4). The age of our patients showed wide variations in the three study groups. The mean age was 50 years both in patients with laryngitis and asthma, but in the pseudoangina group the mean age was significant higher (58 years), suggesting that age is a risk factor for this category of GERD patients. The highest frequency of young patients was recorded in the group with laryngitis, while older patients were most numerous in the group with pseudoangina.

In the literature (5, 6, 7) it is postulated that smokers, obese and dyslipidemic patients are more likely to have GERD. In our study, a quarter of asthma patients were smokers, with a 1.57 times higher relative risk of developing GERD. It appears that non-smoking status may be a protective factor in patients with pseudoangina, but this result cannot be extrapolated to general population. We found obesity in less than a quarter of extra digestive GERD patients, of which half were in group III. The highest percentage of patients with dyslipidemia was found in the group with non-cardiac chest pain. The relative risk to develop GERD of these patients is 3 times higher, which reinforces the idea that dyslipidemia is a factor contributing factor to the development of GERD.

It is well known that typical symptoms of reflux (heartburn/regurgitation) may be absent in patients with extradigestive GERD in a percentage that reaches 50% (8, 9). We obtained similar results, an increased proportion of patients experiencing both typical and extradigestive manifestations being identified in the asthma group.

As to the endoscopic features, lesions of esophagitis were observed in a high percentage of our patients (62.8%), especially in those with pseudoangina, result that is not consistent with studies in the literature (10, 11). Barrett's esophagus has been identified in a minority of cases regardless of dominant extradigestive manifestation. Hiatus hernia, known as a contributing factor in GERD (12), was present in comparable percentages in the laryngitis and asthma group, exceeding 50% of cases only in the pseudoangina group.

The literature data referring to the association of *Helicobacter pylori* infection and GERD are contradictory. Some studies (13, 14, 15) support the protective role of this bacteria in patients with GERD, while other studies (16, 17) postulate that *Helicobacter pylori* infection is a favorable factor in GERD. In our patients, *Helicobacter pylori* infection was identified in just over half of the cases, the lowest frequency being in the group with pseudoangina. This result would suggest that in this category of individuals *Helicobacter* infection may play a protective role in the development of GERD (RR = 0.61), but the result cannot be extrapolated to the general population.

CONCLUSIONS

Our study supports the idea that extra digestive manifestations of GERD are frequent and heterogeneous. There are differences between patients with GERD and chronic laryngitis, asthma and non-cardiac chest pain in terms of demographic, clinical, biological and endoscopic features. We demonstrated that extra digestive manifestations correlate with smoking, obesity and dyslipidemia, as contributing factors. The typical symptoms are absent in about half of extradigestive GERD cases, making the diagnosis being sometimes difficult. It is obvious that *Helicobacter pylori* infection influences the course of GERD, but is still not clear if it is in a positive or a negative way.

CERVICAL SPINE LESIONS IN RHEUMATOID ARTHRITIS PATIENTS (Abstract): **Aim of the study**: to gather clinical and laboratory data on rheumatoid arthritis patients with cervical spine damage (incidence and prevalence, correlation between duration of disease and the time of lesion onset, to assess signs and symptoms and the role of laboratory investigations). The spine is an axial organ with an important role in support and resistance. It is a pillar with a very complex morphological and functional structure. The vertebral column is crossed by many kinematic chains. The main problem of the cervical spine caused by rheumatoid arthritis is cervical instability which describes all cervical lesions that can lead to neurovascular damage or major disturbance of pain generating statics at movement. The evolving disease shows chronic inflammation of the synovium, which is a self-maintained process and an immunologically induced phenomenon. The chronic inflammation of the synovium forms granulation tissue that invades peripheral joints towards the center and causes ligament cartilage and bone damage. **Material and methods:** The present paper investigated cervical spine lesions in 107 rheumatoid arthritis patients who were admitted to the 1st Rheumatology Clinic of Iasi Rehabilitation Hospital between January 2013 and December 2014. Our study focused on assessing signs and symptoms seen in spine affected by rheumatic disease. **Results and Discussions**: the disease causes destructive lesions due to granulomatous infiltration of rachidian structures and medullary sheaths. These lesions lead to damaged discs and instability that produces subluxations and dislocations. The suboccipital region is most affected; in other regions of the spine, high lesions of C4-C5 prevail, where osteolysis damage of spinal apophyses are found. In atlas and axis joints, rheumatoid arthritis causes the inflammation of bursa, synovium and joint capsule and leads to synovial pannus formation. This causes the destruction of cartilage and subchondral bone. Atlantoaxial dislocation is caused by erosive synovitis of atlanto-epistrophic joint, atlanto-odontoid joint and serous bursitis separating the odontoid process from the transverse ligament. **Conclusions:** The dominant symptom of cervical spine damage was pain associated with stiffness and limited joint mobility, muscle stiffness, poor posture. **Keywords:** CERVICAL INSTABILITY, DISLOCATION, DESTRUCTIVE EROSIONS, RADIOLOGICAL CRITERIA.

Cervical spine lesions in rheumatoid arthritis (RA) patients lead to increased physical pain, with local radicular bone marrow involvement that aggravates the functional deficit, worsening the vital prognosis. The impairment of the cervical spine can be explained only partly by its morphological and dynamic characteristics (1).

During the evolutive process, the chronic inflammation of the synovial membrane is a self-maintained, immunologically induced process that leads to the formation of granulation tissue invading peripheral joints towards the center and causing cartilage and bone ligament lesions (2).

Atlanto-axial dislocation occurs at the C1-C2 segment (anterior more than 3 mm between the arch of C1 and the C2 odontoid, with synovial proliferation in the C2 odontoid joint and the anterior arch of C1 that can lead to rupture of the transverse ligament and alar ligaments) (3).

Other lesions of the cervical segment caused by rheumatoid arthritis include: vertical axial subluxation = collapse of the lateral joints between C1 and C2; lateral atlantoaxial subluxation with pain in the frontal and suboccipital region and anterior inclination of the head posture; posterior atlanto-axial subluxation; C2 and C3 are the most commonly affected, while 10 to 20 percent of C3 and C4 are affected. The therapeutic intervention depends on the moment of survey or on the presence or absence of neurological signs (4).

Destructive lesions found in the rest of the cervical spine affect mainly the C3-C4 and C4-C5 segments, the lower cervical spine being less affected (5).

The present study focused on monitoring clinical and laboratory data of cervical spine lesions in rheumatoid arthritis patients.

Aims of the study: The evaluation of the incidence and prevalence of cervical spine damage in rheumatoid arthritis cases hospitalized in the 1st Rheumatology Clinic, Iasi Rehabilitation Hospital, the correlation between the duration of the disease and the onset of cervical spine lesions in rheumatoid arthritis patients, the evaluation of signs and symptoms that occur in the rheumatoid damage of the cervical spine and the the role of laboratory investigations in the diagnosis of vertebral instability (standard radiography, CT examination, MRI examination).

MATERIAL AND METHODS

The study included a group of 107 RA patients who were admitted to the 1st Rheumatology Clinic, Iasi Rehabilitation Hospital between January 2013 and December 2014.

The inclusion criteria were the 1987 ACR classification criteria for RA and the results of the radiological examination (2).

Exclusion criteria included RA patients who did not show clinical or radiological damage to the cervical spine and RA patients with only degenerative changes. The demographic characteristics in the group of patients were initially evaluated through descriptive statistical methods; statistical correlations between clinical and laboratory parameters (e.g. Pearson correlation) were subsequently performed.

T-student and chi-square tests were used for the statistical evaluation of data. They were clinically significant when p is less than or equal to 0.05. The database was systemized with Excel (Microsoft Office), and the statistical analysis used the statistical programs MedCalc and Epi Info 2000.

RESULTS

RA incidence and prevalence are reported differently according to the diagnostic criteria used in population studies (table I).

Out of the total number of 20 (18.69%) RA patients with cervical spine involvement admitted during the study period, 13

(12.14%) were women and 7 (6.54%) were men. A predominant involvement of female patients was noted, showing a regular sex distribution of RA patients and cases with cervical lesions in the sense that female cases are about three times more frequent than male cases. Female gender is a factor of poor prognosis of the disease.

TABLE I
Incidence and prevalence in the study group

Year	2013	2014	Total
Total number of RA patients	46	61	107
RA with cervical damage - new cases	6	9	15
RA with cervical damage - reappraisal	2	3	5
Incidence of cervical damage in RA patients	13.33%	20.00%	33.33%
Prevalence of cervical damage in RA patients	17.39%	14.75%	32.14%

54.4% of the study group patients were from urban areas, possibly explained by the higher medical visit rate of the urban group. The values related to the duration (in years) of RA were dispersed, ranging from 0 to 35 years of disease, most patients (64.5%) being in the group with a duration of less than 5 years (table II).

TABLE II
Distribution of the study group according to the duration of the disease

Years	< 5	5-10	10-15	15-20	>20
Patients in the study group (%)	61.31	14.50	5.60	3.40	4.40

The study group patients were aged over 45 years and cervical lesions were present in patients with a duration of the disease of at least 10 years in cases with onset before the age of 65 and occurred early in patients with senile RA. Damage to the cervical spine was higher in elderly patients with a longer duration of the disease and especially in the more severe types of disease.

Specific symptoms occurred gradually in most patients from a period of several months to several years. The dominant symptom was joint pain exacerbated at night associated with prolonged morning stiffness and swelling of various joint areas that have led to functional impairment, the higher, the more regions were affected by arthritis. Several clinical onset forms were observed, i.e. monoarticular, oligoarticular, polyarticular. Other onset forms were extraarticular manifestations such as muscle pain, tendonitis or ductal syndromes (especially carpal tunnel syndrome). The polyarticular type of disease onset with rapid development of deformities and joint ankyloses was mostly seen in patients with cervical damage.

TABLE III
Distribution of general signs in RA patients

General signs	%
Asthenia, fatigue	97
Loss of appetite	45
Transient arthralgia	91
Raynaud's syndrome, acrocyanosis	49
Weight loss	12
Irritability	83
Depression, insomnia	85

The main clinical manifestations were pain, swelling, morning stiffness and functional discomfort (table III).

Inflammatory cervicalgia and cervical stiffness was present in all study group patients studied, but the elderly with senile RA, aged 65 years, cervicalgia showed also degenerative changes. Signs suggesting the localization of the rheumatoid process at the cervical level in the study group were found in varying proportions (tab. IV).

The dominant element was cervical and cervical-cephalic pain associated with stiffness of the extensor, trapezius or sternocleidomastoid muscle. Almost half of the patients showed a poor posture of the cephalic extremity with slight anteflexion.

16% of patients had severe neurological damage caused by cervical changes, while the altered sensitivity seen in the dermatomes of the cervical plexus roots was frequent.

TABLE IV

Symptoms of cervical damage in RA patients

Clinical signs of cervical damage in rheumatoid arthritis	%
Scalp tenderness	66%
Tenderness of the spinous apophyses, cervical chain	95%
Altered sensitivity of the cervical region and upper limbs	45%
Muscle tenderness	74%
Muscle weakness in regional muscles and upper limb end	54%
Fasciculations	1%
Transient hearing loss	3%
Sensory ataxia	1%
Sensitivity of the carotid sinus	9%

The study of global and segmental mobility of the cervical spine showed a severe limitation of movements in the upper region in 37% of the cases and an overall mobility limitation in 41% of the patients.

TABLE V

Extraarticular manifestations in RA study group patients

Extraarticular manifestation	%
Subcutaneous nodules	39.7
Tenosynovitis	31.0
Myopathy	36.3
Cardiomyopathy	6.1
Rheumatoid lung	24.3
Pleurisy	0.93
Pulmonary fibrosis	7.5

In patients with severe cervical damage, extraarticular manifestations included changes in the skin, subcutaneous tissue and juxtaarticular tissues, respiratory and cardiovascular systems (table V).

Skin manifestations – 39.7% subcutaneous nodules were seen in patients with cervical lesions. This was correlated with a relatively long duration of the disease and with severe forms of the disease. They were associated with seropositive forms of the disease and with other systemic manifestations such as rheumatoid lung.

Nonspecific cutaneous manifestations (pale skin, hypopilosity, dull brittle nails, hyperpigmentations) were also seen. Some of them express the inflammatory anemia caused by the long evolution of the disease in the selected patients.

Skeletal muscles and tendons - the study group patients often showed myalgia (in the shoulder girdle) and muscle weakness,

clinically expressed as muscle atrophy caused by inactivity, secondary to the joint pain of the disease. The anatomo-pathological basis was represented by degenerative lesions of muscle fibers.

Respiratory manifestations - multinodular rheumatoid lung, radiographically shown, clinically manifested as dry cough, moderate dyspnea and intermittent hemoptysis were present in 14 (58.3%) patients. Pleurisy was observed in 1 (0.93%) patient; as the pleurisy was quantitatively reduced, it was reabsorbed following appropriate antibiotic and anti-inflammatory therapy.

Cardiovascular manifestations - difficult to assess, given that patients in the study group were over 45 years old and physiological changes of involution are closely intricated with pathological changes that cannot be properly classified. Chest pain, dyspnoea on exertion or tachycardia are difficult to interpret. Arterial hypertension was present in 63% of patients.

Digestive manifestations - clinically, 14 (35%) patients had hepatomegaly at baseline. Following administration of NSAIDs, 31% of patients had epigastralgia and heartburn. Gastric or gastroduodenal ulcer, radiographically shown, was present in 3 (15.00%) patients.

Neurologic manifestations - compressive neuropathies, such as carpal tunnel syndrome, were found in 9 (45%) patients and resulted from existing periarticular changes. The manifestations were more pronounced in the dominant limb. Damaged brachial plexus roots gave rise to radicular syndromes characterized by pain, paresthesia, hypoesthesia in the corresponding dermatome and the decrease of osteotendon reflexes. A significant percentage of patients showed this manifestation. These clinical changes were present mainly in patients with specific cervical radiological changes, such as subaxial dislocation. Cervical-brachial neuralgia was seen in 7 (6.54%) patients.

Facial paralysis was observed in 2 (10%) patients, probably caused by the damage of the spinal nucleus of the trigeminal nerve, as patients had atlantoaxial dislocation. Several patients showed symptoms of dysphagia and dysphonia, which can be attributed to altered hypoglossal nerve (XII), vagus nerve (X) and glossopharyngeal nerve (IX). By using the Redlung-Johnell method, radiological changes such as vertical atlanto-axial dislocation were seen in these patients.

Renal manifestations. The research showed that 2 (10%) patients had a proteinuria of 1.5 g / 24 hours, one patient having a proteinuria of 1g / 24 hours. A high frequency of urinary tract infections was seen in women (38.6%) due to associated risk factors found in RA patients with decreased immune defense, hormonal changes, frequent hospitalizations and consumption of NSAIDs.

Hematologic changes - anemia was present in 17 (8.00%) patients (out of the total number of 20 patients). The most common cases showed normocytic and hypochromic anemia, as well as and hyposideremia; serum Fe values were low in some patients. The anemia seen in these patients can be attributed to the long evolution of the inflammatory disease and it is associated with iron absorption disorders, moderate decrease of erythropoiesis, hemolysis and blood loss.

3% of the study group patients had clinical manifestations of diplopia that might be caused by the damage of the abducens nerve (VI).

The following laboratory parameters and their correlations were followed in patients with cervical lesions caused by RA: biological inflammatory syndrome,

immunological changes - rheumatoid factors, standard radiological examination - flexion / extension; CT and MRI were used in patients with neurological symptoms.

Inflammatory syndrome - the assessment of ESR and CRP values, the blood count were useful for both diagnosis and the survey of the progression of the disease by determining their dynamics.

Anterior atlanto-axial dislocation was the most common form of cervical instability (65% of study group patients). Combined dislocations such as anterior atlanto-axial dislocation associated with the subaxial dislocation were far less numerous, 7 (35%) patients, as compared with 13 (65%) patients with anterior atlanto-axial dislocation. Other forms of dislocations were much less common.

The radiological examination has shown fractures of the odontoid in 1 patient; erosions of the interapophyseal joint in 4.2%; odontoid secondary osteosclerosis in 2.5%; the appearance of diffuse osteoporosis was associated with about 47% of the total number of patients. CT was performed in 4 patients and MRI in 3 patients.

DISCUSSIONS

Anterior atlanto-axial subluxation is the most frequent classical involvement of cervical spine in RA. The profile radiography of the cervical spine, C1-C2 - centered, shows a distance of more than 3 mm between the posterior edge of the anterior arch of the atlas and the anterior edge of the odontoid apophysis. The anterior subluxation of the atlas to the axis is possible due to the rupture or distension of the transverse and cruciform ligaments, following the chronic inflammation of the atlanto-axial joint (6, 2).

Subluxation causes the narrowing of the retro-odontoid part of the spinal canal and the compromise of the neuraxis at the bulbo-medullary junction.

Clinically, the alteration of this joint can be completely asymptomatic, with a latent evolution, or may lead to severe cervical pain, high and posterior with inflammatory rhythm. Neurological complications are quite rare and include Lhermitte's sign or neurological signs of the upper limb: sensory disorders, movement disorders (3,4).

The literature reports also cases of sudden death (5), mostly following road accidents or during intubation for general anesthesia. Therefore, the arthritic condition must be systematically investigated before any surgical intervention (4,8).

Our findings showed also that the positive diagnosis is based on radiological examination (profile radiography of the cervical spine, C1-C2-centered, dynamic, flexion and extension) and on CT examination (a posterior detachment of the odontoid apophysis related to the anterior arch of the atlas is observed on the cross sections of the spine) similar to the reports of other authors (11,12).

The cervical spine damage in RA might involve also the middle and lower spine under the form of posterior interapophyseal arthritis. This could cause joint slipping or subluxations between vertebral bodies. These lesions are easily noticed on dynamic flexion / extension radiographs. These areas of the cervical spine are affected in 15% of the cases. The results concur with literature data already mentioned (13,14).

CONCLUSIONS

Our study showed that cervical spine lesions lead to increased physical pain, with local radicular bone marrow involvement that aggravates the functional deficit, worsening the vital prognosis.

The main disorder of the cervical spine

damaged by rheumatoid arthritis is cervical instability. The damage of the cervical segment caused by RA occurs late in the evolution of the disease, when destructive cartilage and bone lesions, axial deformities, extensive muscular atrophy and, in some cases, even fibrous or bony ankylosis are present.

The dominant symptom of cervical spine damage was pain associated with limited joint mobility, muscle stiffness and poor posture.

SELENIUM STATUS IN AUTOIMMUNE THYROIDITIS (Abstract): Selenium (Se) is an important element that exerts its effects through selenoproteins. The thyroid gland has the highest Se concentration and specific selenoprotein enzymes families are crucial in the thyroid hormone metabolism. There is little evidence on the link between Se and thyroid autoimmune disease, therefore future studies are required to elucidate the nature of this association. **Aim**: To evaluate the Se status in euthyroid subjects with autoimmune thyroiditis**. Material and methods**:FromJanuary 2014 to January 2015 we recruited 100 consecutive euthyroid subjects with autoimmune thyroiditis, living in the same region and with normal iodine intake. Serum concentrations of Se, thyroid antibodies (antithyroperoxidase –TPOAb – and antithyroglobulin – TgAb), thyroid-stimulating hormone (TSH), and thyroid ultrasound were performed in all patients. **Results:** Mean age of the study group was 48.87±12.83 years, range: 18-82 years. Since thyroid pathology is more frequent in the 5th – 6th decades of life we selected the age of 50 for the comparative analysis of the results (51% of patients were under 50). No statistical age-group differences in antibody levels were found: mean TPOAb = 420.95 IU/ml, p=0.840; mean TgAb = 327.98 IU/ml, p=0.977. TSH mean was 2.14 µIU/ml, with no significant age-group differences (p=0.176). Se levels ranged between 8.05 - 998.50µg/ with a mean value of 294.96µg/L and no significant differences between age groups (p=0.158). Thyroid ultrasound showed inhomogeneity in 89%, nodules in 35% of patients, and a mean thyroid volume of 11.72ml, with no significant age-group differences (p=0.366). The low TSH levels were associated with low Se levels in 11.6% of cases, but the direct correlation was statistically insignificant (r = 0.116; R^2 = 0.0161; p = 0.371). Depending on TSH percentiles, mean Selevels showed no significant differences, however pointing out the highest mean value at the 25th percentile (F = 0.441, df = 61, p = 0.646). A negative correlation trend was found between Se and TPOAb (r=-0.2276) or TgAb (r=-0.2190) but lacking statistical significance (p=0.099). **Conclusion:** Our results showed a weak negative correlation between Se and antithyroid antibodies, suggesting that selenium supplementation may improve the course of thyroid autoimmunity. **Keywords**: SELENIUM, AUTOIMMUNE THYROIDITIS.

Selenium (Se) was first isolated in 1817 by Jacob Berzelius (1), and its name derives from Selene – goddess of the moon. Se is a metalloid present in the environment, water, soil and air, generally in very low concentrations (< 1µg/g) (1) and is an essential element for human health.

Se has a concentration-dependent effect in the body, being an antioxidant at nano- or micromolar levels while in higher concentrations it has a prooxidant effect.

The normal plasma Se concentrations of range between 60 and 120µg/l or 0.8 ± 0.36µmol/l being related to its intake through diet and the daily dose should not exceed 400 µg/day, dose at which toxic effects were observed (2).

Se deficiency can affect human health in different ways. The severe endemic deficiency is associated with Keshan disease (congestive cardiomyopathy) and Kaschin-Beck disease (chronic, endemic osteochondropathy), and the mild one with various limited expression of Se-dependent enzymes. Causes of deficiency are dietary low intake and poor intestinal absorption. Selenosis is the most common disease as a result of over limit intake of Se from food (3).

The majority of Se in tissues is found in proteins (seleno-proteins, selenotrisulphides and other acide-labile Se compounds) (4). In humans, the thyroid gland has the highest Se concentration as a constitutive part of Dio 1 and 2 thatconvert thyroxine (T4) to triiodothyronine (T3); Gpx 1 and 4, which protect thyreocytes against H_2O_2 released during thyroglobulin iodination; Gpx3, regulating H_2O_2 concentration in the lumen of thyroid follicle; selenoprotein P and Txnrd 1, having an antioxidant effect (5).

In normal nutritional conditions, the liver is the primary source of plasma T3, due to liver deiodination of T4 by Dio 1 (which actually contributes to the release of T3 by the thyroid). In Se deficiency, the primary source of T3 is the thyroid by increasing thyroid activity of Dio1 which allows maintaining normal concentrations of plasma T3 despite reduced activity of hepatic Dio (6).

Selenium deficiency leads to a decrease in GPx activity that results in the accumulation of H_2O_2 in the thyroid and thus enhancing apoptosis. Since H_2O_2 is essential in the synthesis of T3 and T4, its accumulation could be the activator of increased thyroid production of T3 and T4. Probably Dio 1 is required to maintain an optimum T4/T3 balance in these conditions (6).

Selenium was shown to have an important role in lymphocytic chronic thyroiditis. Most authors consider that Se affects the autoimmune system by controlling the production of ROS (Reactive Oxygen Species) and Se supplementation determines a stimulating activity on glutathione peroxidases and thioreductases. Another path in which Se is involved in autoimmune thyroiditis may be by inhibiting the expression of HLA-DR molecules (7, 8).

Currently, there are no ways to stop the autoimmune process in chronic thyroiditis; levothyroxine treatment only addresses to the consequences of autoimmune aggression (9).

Given current knowledge, selenium therapy to reduce aggression and to prevent autoimmune thyroid dysfunction, remains the only therapeutic alternative, whose effectiveness needs to be supported by more evidence.

MATERIAL AND METHODS

We conducted a one-year prospective study (January 2014 - January 2015) in the

Department of Endocrinology of the "St.Spiridon" Hospital Iasi. One hundred consecutive subjects with euthyroid autoimmune thyroiditis and normal iodine intake were selected. Serum concentrations of TPOAb, TgAb, thyroid-stimulating hormone (TSH), Se and thyroid ultrasound were performed in all patients. In a second phase, Se was randomly administrated to half of these patients and re-assessed them after 3 months.

Inclusion criteria: female patients aged 18 to 2 years with normal thyroid function (TSH =0.4-4μIU/ml) and autoimmune thyroiditis (TPOAb>35UI/ml or/and TgAb> 40UI/ml) able to sign informed consent. All patients included in our study signed the informed consent. *Exclusion criteria*: major co-morbidities making it difficult to participatein the study, thyroid treatment (LT4 or anti-thyroid drugs) previous or at the time of enrollment; pregnancy or breast-feeding; malabsorption or consumptive syndromes, other autoimmune diseases, and intake of selenium supplementation above 70 μg/day; inability to read or understand Romanian; or lack of informed consent.*Variables studied*: age, sex, titersof TPOAb and TGAb, TSH, volume (V) and echostructure (E) at thyroid ultrasound, and plasma Se levels.

TSH and thyroid Abs were measured by chemiluminescence at the hospital laboratory.

Se measurements were performed by atomic absorption spectrometry using the GF with platform HR-CS-AAS contra 600 AnalytikJena (10). The method we used involves several steps: fresh blood samples were preserved by freezing at -25° C; they were defrosted and homogenized before metal digestion; metal digestion for Se analysis also had several steps. A mixture of 1ml total blood with 3ml of nitric acid 65% and 1ml hydrogen peroxide 30% was allowed 15 minutes to react. To realize the digestion process we kept the samples at 145°C for 5 minutes, at 190° for 10 minutes and finally at 100°C for 10 minutes. After the digestion process the samples were transferred into 25 ml decontaminated Duran volumetric flasks. The flasks containing the samples were filled with ultrapure water up to a volume of 25ml,shaked few times and then the content was transferred in 15ml bottles for the final metal analysis.

The collected data were processed and interpreted by using the SPSS 18.0 software and statistical and mathematical tests.

RESULTS

Mean age of the study group was 48.87±12.83 years, range: 18-82 years. The study group was divided into two groups according to their age, with age 50 as the demarcationpoit, justified by the fact that thyroid pathology is more frequent after the 5th–6th decade of life. 51% patients were aged under 50 years. No statistical age-group differences in antibody levels were found: mean TPOAb = 420.95 IU/ml, p = 0.840; mean TgAb = 327.98 IU/ml, p = 0.977. For TSH the mean value was 2.14 μIU/ml with no significant age-group differences (p=0.176). Se levels ranged between 8.05-998.50 μg/L with a mean value of 294.96 μg/L (p=0.158). Thyroid ultrasound showed inhomogeneity in 89%of patients, nodules in 35%, and a mean thyroid volume of 11.72 ml (p=0.366) (tab. I).

Depending on TSH percentiles, mean Se levels showed no significant differences, however pointing out the highest mean value at the 25th percentile (F = 0.441, df = 61, p = 0.646). A negative correlation trend was found between Se and

TPOAb (r=-0.2276) (Fig.1) or TgAb (r=-0.2190), but lacking statistical significance (p=0.099) (fig. 2).

The low TSH levels were associated with low Se levels in 11.6% of cases, but the direct correlation was statistically insignificant (r = 0.116; R^2 = 0.0161; p = 0.371) (fig. 1).

The same result (negative Se-ATPO Ab correlation) was obtained when we divided our study group into 3 subgroups depending on Se levels (tab. II).

DISCUSSION

Se is an essential micronutrient in many aspects of human health, which plays a major part in optimal endocrine response, immunomodulation and inflammatory process. The most frequent disease involving the thyroid gland is chronic autoimmune thyroiditis, an inflammatory process which progressively destroys the gland. Several studies have examined the potential benefits of Se in this disease to assess if its supplementation may be effective in in-

creasing the antioxidant defenses (11).

In the present study we measured Se levels in the blood of euthyroid patients with autoimmune thyroiditis. This is the second study which provides information on Se status in Romanian patients with autoimmune thyroiditis. The fist data on Se level in the Romanian patients were provided by a multicenter study published in 2014 (12) which recruited patients from four European countries (Greece, Romania, Austria, Italy) (tab. III).

TABLE III
Selenium status in different European countries

Author	Country	Selenium levels(plasma µg/l)	
		Patients with TAI	Patients without TAI
Krassas, Pontikides, Tziomalos*et al*. Se status in patients with autoimmune et non-autoimmune thyroid disease from four European countries	Italy (2014)	106.0 ± 41.9 (n=13)	116.8 ± 34.2 (n = 56)
	Greece (2014)	81.3 ± 50.7 (n=81)	82.3 ± 27.8 (n = 56)
	Austria (2014)	83.1 ± 31.2 (n=36)	93.4 ± 31.2 (n = 25)
	Romania (Timisoara 2014)	86.6 ± 23.3 (n=30)	80.4 ± 31.0 (n = 22)
Present study, The effect of Se supplementation on antioxidant status, hormonal, autoimmune and ultrasonographic profile in euthyroid patients with chronic autoimmune thyroiditis	Romania (Iasi 2015)	294.96 ± 241 (n=100) blood	ND

When comparing the results of these two studies we found that the Se levels reported in 2015 were higher than those from the multicenter study. This difference can be explained by the fact that we used total blood which contains more Se than plasma. In our study Se was determined by atomic absorption spectrometry (see methods). The method we used is an original one but there are various methods for Se determination: nuclear activation analysis (NAA), elecrothermal atomic absorption spectrometry (ET AAS), hydride generation atomic absorption spectrometry (HG AAS), fluorimetry, X-ray fluorescence analysis (XFA), and gas-liquid chromatography (GCL) (Bem EM). Chromogenic reagents used for Sedetermination by various spectrophotometric methods are: dithiozone, chromo tropicacid, J-acid, Variamine Blue (12).

Usually, these methods are used to determine Se in plasma, serum, whole blood and other tissues. Se concentration in the serum and plasma have similar values (plasma contains 81% of the Se of whole

blood and 94% of serum) and correlates with Se ingestion. Se in whole blood varies less and correlates better with GPx(3). The obtained Se levels, even if the same tissue is used, can vary depending on method. Another variable is the number of patients (the 2015 Iasi study had a greater number of patients) and the heterogeneity of the study group. The iodine intake is also very important. Anamnestically, our patients had a normal iodine intake. Previous studies reveled that Moldavia is aniodine deficient region, except Iasi, where the iodine intake is normal (13).

Levels of Se also vary by geographic region(type of soil) which influences the dietary Se intake. The dietary Se intake is in the range 7-4990 mg/day, with different mean values for each geographical area (40µg/day in Europe, 93µg/day in women and 134µg/day in men in the USA). Also, the dietary Se concentrations are dependent on the soil Se content, form and distribution of Se in foods (Se from plant source foods is a more bioavailable form than animal source foods) (13).

China, India, Middle–East and some European countries have a very low content of Se in soil resulting in Se deficiency in the local population (3). Soilsof the driest regions concentrate high quantities of Se and alkaline soils release more Se than the acid ones (3).

Selenium content of foodstuffs varies in a broad range between countries, depending mainly on selenium content in soils and its availability (bioavailability) for plants. The bioavailability for plants depends mainly on the chemical forms of selenium in the soil, but is also influenced by some physicochemical parameters of the soil. The absorption of Se^{+6} is generally higher than that of Se^{+4}. The selenium content in animal products depends on its content in the diet consumed by the animals (14).

In most countries, legumes,cereals and derivatives are the main source of selenium intake, due to their predominance in the diet. In few cases, meat, poultry and seafood are the main contributing food categories to selenium intake (14).

Agricultural activities can influence Se levels in foodstuffs. In some areas of the world Se has been added to fertilizers in order to increase Se levels in cultivated plants and indirectly improve selenium status in humans (3).

As to our study it is difficult to integrate the results of Se determinations because we donot have the normal Se levels for our population and we donot know the content of Se in our soil. So we compared our results with those reported by other European countries (Table III). The different results are accounted for by the differences in dietary intake and soil content.

It is difficult to obtain unbiased estimates of dietary trace-element intake, no matter of the epidemiological method used. Due to high variability in Se content of different foodstuffs and interindividual diet variations, the procedure for estimating Se dietary intake is questionable (14). The recommended adult daily Seintake varies considerably between authors, countries and organizations. Schrauzer and White (cited by Dharmasena, 2014) estimated a daily Se intake per person in the range 90-168 µg. In Asia, Africa and many European countries the daily Seintake is below the recommended dose. Se deficiency has negative consequences mostly in seniors, pregnant and lactating women, growing and developing children (3). In order to provide a safe total Se intake the reference dose (RfD) from all nutritional sources for a 70 kg adult has

been set at 350µg/day, corresponding to 5 µg Se/kg body weight/day (11).

We also found that Se status correlated positively with age, which is in line with the findings from most similar studies (11).

Regarding TPO Abs, the available data show that in 11 Se supplementation trials in patients with autoimmune thyroiditis, 7 have shown benefit and positive effects on serum TPO-Ab concentrations. Another fact is that high Se levels in the blood are associated with low TPO levels (15).

Our study revealed a negative correlation between Se and TPO – Ab but lacking statistical significance (p=0.099). Our study group was divided into 3 groups according to Selevel (and compared them with the normal Se levels in Europe - plasma Se =60g/L -120g/L). We found no significant differences between TSH and ATPO values depending on Se level. Instead, for low Selevels we obtained a negative correlation with ATPO-Ab, which suggests the possible benefits of selenium treatment in autoimmune thyroiditis (tab. II).

New studies are required to evaluate the evolution of antithyroid antibodies during Se supplementation and the development of reliable methods for direct determination of Se level in the body and especially the amount necessary to ensure homeostasis and prevention of thyroid specific autoimmune pathology. Also, little is known about the effect of mild selenium deficiency in the context of normal iodine intake (situation specific for our country).

CONCLUSION

In our study the low Selevels were associated with high TSH levels, suggesting apossible involvement ofselenium inthyroid function.

Our results showed a weak negative correlation between selenium and antithyroid antibodies, so selenium supplementation may improve the evolution of thyroid autoimmunity.

Meaningful clinical outcomes should be demonstrated before Se supplementation can be routinely suggested in patients with thyroid autoimmunity.

NEWS

CARDIAC REHABILITATION AFTER SURGICAL CORRECTION OF CONGENITAL HEART DISEASE

Comprehensive cardiac rehabilitation is an important element of the comprehensive management of grown-up congenital heart disease patients after surgical correction of congenital heart disease but access to this treatment is still limited. To assess the effect of a comprehensive cardiac rehabilitation program on physical capacity, exercise tolerance, quality of life, and severity of depressive symptoms in grown-up congenital heart disease patients long-term after surgical correction of congenital heart disease. Implementation of a comprehensive cardiac rehabilitation rogram improves physical capacity, exercise tolerance, and quality of life and reduces depressive symptoms in patients late after surgical correction of congenital heart disease. Introduction of such programs seems reasonable as a supplement to the holistic care for grown-up congenital heart disease patients (Gierat-Haponiuk K, Haponiuk I, Szalewska D, Chojnicki M, Jaworski R, Niedoszytko P, Leszczyńska K, Bakuła S. Effect of complex cardiac rehabilitation on physical activity and quality of life during long-term follow-up after surgical correction of congenital heart disease. *Kardiol Pol.* 2015;73(4):267-73).

TUBEROUS SCLEROSIS – PRENATAL DIAGNOSIS OF CARDIAC PHABDOMYOMA (CASE REPORT) (Abstract). Primary cardiac tumors are rare in medical practice, with a prevalence of 0.0017-0.28% in autopsy examinations. In intrauterine life, the incidence of cardiac tumors has been reported to be of approximately 0.14%. Rhamdomyoma is the most frequent tumor formation during fetal period and childhood, accounting for 70% of all primary tumors in the fetus, neonate and infant. Diagnosing heart rhabdomyomas occurs most often by accident during fetal morphology at 22 weeks. We will present a case of a newborn diagnosed with fetal echocardiography in the 23 week of gestation having multiple cardiac tumors. **Keywords**: TUBEROUS SCLEROSIS, FETAL ECOGRAPHY, HYPO-MELANOTIC MACULES, CARDIAC RHABDOMYOMA.

Advances in medicine and technology made it possible to diagnose a growing number of diseases, many of them in the fetal period.

Cardiac tumors can be benign or malignant having as a starting point muscle layers or pericardium. These can be primary or secondary, of the metastatic type.

Primary cardiac tumors are rare in medical practice, with a prevalence of 0.0017-0.28% at autopsy examinations. In intrauterine life, the incidence of cardiac tumors has been reported to be approximately of 0.14%. Most of them have a benign nature, only 10% of them being malignant (1, 2, 3, 4).

Rhabdomyoma is the most frequent tumor formation during fetal period and in childhood, accounting for 70% of all primary tumors in the fetus, newborn and infant (5,6). It is most often located in the ventricles but it may also originate in the atria (7, 8).

Diagnosing heart rhabdomyomas occurs most often by accident during fetal morphology at 22 weeks. While the association between tuberous sclerosis and heart rhabdomyomas has been recognized, association with only one tumor formation cannot lead to the diagnosis of tuberous sclerosis.

Tuberous sclerosis is a monogenic, multisystemic disease with dominant autosomal transmission, high penetration and variable expressivity, characterized by skin, cerebral and characteristic visceral manifestations.

CASE REPORT

We are presenting the case of a female newborn, born by caesarean section, cranial presentation, with a birth weight of 4000 g

and one minute Apgar 8 score, admitted to the Cardiology Department of ”Sf. Maria” Emergency Children's Hospital in Iaşi for seizures accompanied by perioronasal cyanosis.

From the hereditary familial information, we could observe that both parents are apparently healthy and the patient’s brother was postnatally diagnosed with pyloric stenosis.

Regarding pregnancy history, we found that the mother was diagnosed with chickenpox at 23 weeks of gestation.

The obstetrical control performed at 26 weeks of amenorrhea, the mother did a fetal ultrasound and morphology, based on which the doctor identified echogenic images in the brain and in the heart.

In the brain, there was a bilateral presence of non-homogenepus hyperechogenic images, imprecisely demarcated: at the right hemisphere in temporal lobe measuring 11/6 mm and in frontal lobe 4/4 mm and in the left hemisphere, in frontal lobe measuring 10/7 mm and 5/4 mm.

In the heart, the obstetrician noted the presence of a heterogeneous hyper echogenic images, vaguely defined, with dimensions of 6/4 mm in the thickness of the right ventricular wall. He also noticed an image with the same specifications having 13/7mm (fig. 1, 2) in the thickness of the papillary muscle of the left ventricle.

Therefore, based on fetal morphology, the obstetrician established the diagnosis of cardiac tumor (rhabdomyoma).

Postnatally, an echocardioecography was performed that revealed multiple formations, most in the left ventricle, measuring 18/16/12 mm, with polylobate contours, with implantation to the side wall of the ventricle. In the interventricular septum, in the apex and in the thickness of the myocardium, three other formations of infracentimetric size and in the right ventricle, another oval image of 6/7 mm under septal cusp of the tricuspid.

Fig. 1. Fetal echocardiography, hyperechoic formation, non-homogenous in the right ventricle.

Fig. 2. Fetal echocardiography –presence of the two imprecisely defined hyperechogenic on the right and left ventricle.

Clinical examination during last hospitalization showed that the patient had good general condition, pale skin, perioronasal cyanosis, multiple hypopigmented macules, spread on the entire body surface, the largest measuring 2/6 cm, located on the left flank. No murmur was detected by listening. The abdomen was supple, depressive, mobile with respiratory movements. In

terms of neuromotor activity, the child was developed normally.

Biologically, we could note the presence of a mild thrombocytosis and hyposideremia.

Performed electroencephalogram showed a spontaneous route with motion artifacts, with releases of ample waves in all derivations.

Electrocardiography revealed a sinus rhythm with a 160-170 beats/minute, electrical axis 60 degrees, PQ =0.12s, with normal morphology, QT=0.26s (upper limit).

Transfrontal ultrasound was normal, no modifications in the brain substance were found.

As the child has numerous seizures, treated at that moment with Tonotil, we recommended a neurological examination that showed depigmented patches of different sizes on the trunk and limbs, epileptic spasms in extension and generalized motor seizures. Therefore, the pediatrician made the diagnosis of Bourneville tuberous sclerosis and West syndrome with lesions and recommended a CT brain scan.

Since tuberous sclerosis is a multisystemic disease with dominant autosomal transmission, we also recommended that should be performed that raised again the suspicion of Bourneville tuberous sclerosis. Samples for DNA tests were collected that were transferred for confirmation to a specialized laboratory.

Also, it was recommended to parents that an echocardiography should be made to see if any of them showed changes typical to tuberous sclerosis. Cardiological investigations of family members showed no evidence of cardiac tumors in none of them.

The ophthalmologic examination that we recommended, including fundus examination, revealed no occurrence of tumors in the retina.

Ultrasounds performed during hospitalization showed the presence of left ventricular of tumors measuring 17.5/11.1 mm and 25.2/16.7mm. On the side wall of the right ventricle, we were able to observe two growths of 4.2/1.8 mm and 3.6/1.8mm. Inside the right ventricle, a tumor of 8.1/6.7 mm was found, and at the tip of the left ventricle two tumor formations of 10.7/4.3mm and 12.9/3.1-5.3mm, respectively. The patient also showed left ventricular dysfunction and permeable oval foramen (fig. 3, 4, 5).

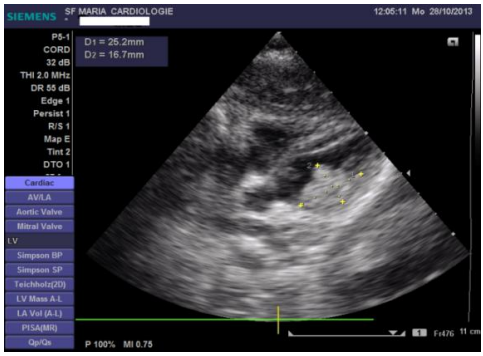

Fig. 3. Echocardiography - subcostal section. Shows numerous hyperchogenic formations in the right and left ventricle

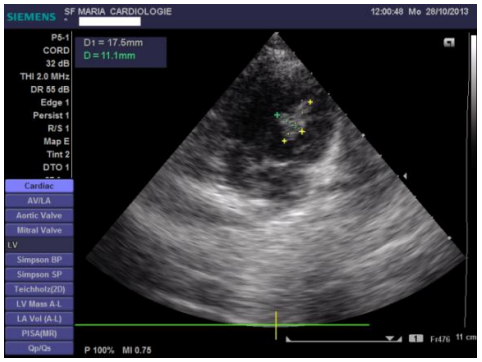

Fig. 4. *Echocardiography apical 4 chamber view – shows 12 tumoral formations*

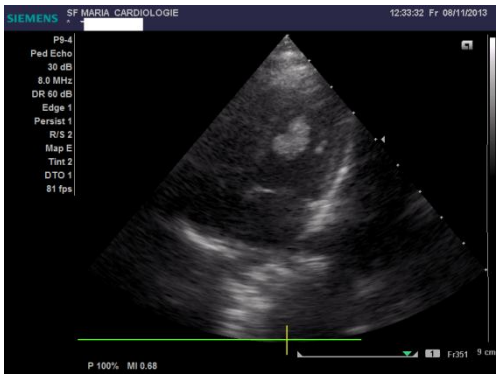

Fig. 5. Echocardiography, apical 4 chamber view. Tumor formations at the top of left ventricle

The performed thoracoabdominal CT scan showed an expansive formation, solid density, iodophile, natively and post-contrast applied intravenously homogenous, well defined, with regular outline, which occupies the upper floor and the floor above middle mediastinum, with upper sizes 24/65/45 mm having no effect on the mass and with anterior relation to anterior chest wall; posterior relation to trachea, the internal carotid artery, vascular pedicle and the front of the heart; lateral to pulmonary pleura and superior to a plan section passing through the inferior edge of the clavicle (fig. 6, 7).

Fig. 6. Formations in upper floor and middle floor of anterior mediastinum

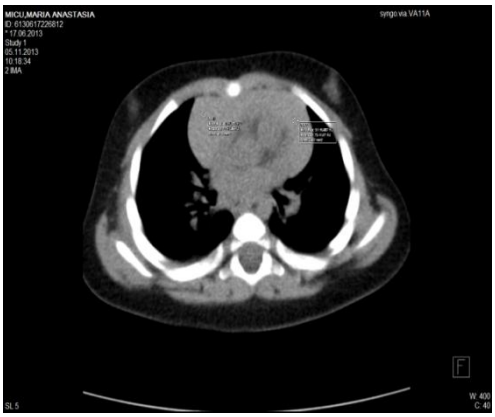

Fig.7. Thoracoabdominal CT scan – showing mediastinal formations

CT brain examination showed hyper dense areas after intravenous contrast, disseminated to the brain substance, with varying sizes, the largest of 9/7mm, in the left frontal lobe, without mass effect on adjacent structures (fig. 8).

Fig. 8. Brain CT showing hypersense areas after CIV in brain substance

Final diagnosis was: Bournevile tuberous sclerosis that was attributed to changes in the skin, presence of tumors in the brain and heart, permeable oval foramen, left ventricular dysfunction and West syndrome with lesions.

DISCUSSION

Rhabdomyomas are the most common

cardiac tumors found in newborn and children at a rate of 51-96% associated with tuberous sclerosis (9).

While the association between tuberous sclerosis and heart rhabdomyomas has been recognized, the association with only one tumor formation cannot diagnose tuberous sclerosis.

TABLE I
Positive diagnostic criteria for tuberous sclerosis

Major criteria	Minor criteria
1.Hypomelanotic macules (≥3, at least 5-mm diameter) 2. Angiofibromas (≥3) or fibrous cephalic plaque 3. Ungual fibromas (≥2) 4. Shagreen patch 5. Multiple retinal hamartomas 6. Cortical dysplasias 7. Subependymal nodules 8. Subependymal giant cell astrocytoma 9. Cardiac rhabdomyoma 10. Lymphangioleiomyomatosis (LAM) 11. Angiomyolipomas (≥2)	1. "Confetti" skin lesions 2. Dental enamel pits (≥3) 3. Intraoral fibromas (≥2) 4. Retinal achromic patch 5. Multiple renal cysts 6. Nonrenal hamartomas

Detecting multiple growths in the heart during fetal period diagnoses the Bourneville syndrome before the appearance of skin signs or seizures in the postnatal period (10, 11).

Tuberous sclerosis is a monogenic, multisystemic disease with dominant autosomal transmission, high penetration and variable expressivity.

This occurs in response to mutations of two tumor suppressing genes, TSC1 coding hamartin and TSC2 coding tuberin. TSC2 gene is located near the gene involved in the production of polycystic kidney disease, which in case of larger deletions (seen in 2% of cases) makes patients show both pathologies.

To confirm the clinical diagnosis, the criteria of "The 2012 International Tuberous Sclerosis Complex Consensus Group" are used. The presence of two major or one major criteria makes the diagnosis to be certain (15).

In the presented case, the clinical diagnosis clinical diagnosis was made on the presence since intrauterine life of heart rhabdomyomas, confirmed later postnatally by both echocardiography and by the CT examination, the presence of growths in the brain and hypomelanotic macules (>3) (13,14).

The following complications may occur in the future: arrhythmias, most commonly ventricular, loss of myocardial function due to the increase of the tumor mass located in the side wall of the left ventricle, in the papillary muscles and in the interventricular septum that may be conducive to decreased cardiac output and congestive heart failure. It has been observed that the Wolf-Parkinson-White syndrome has a higher incidence in patients with tuberous sclerosis, it is about 2% (1.12). Depending on the size of the tumor and the appeared complications, death may occur in some cases.

CONCLUSIONS

The evolution of techniques detecting congenital defects or diseases in the early stages allowed the pre-natal diagnosis of

numerous pathologies. Today, the suspicion of tuberous sclerosis may be raised since the pre-natal period, if the presence of cardiac rhabdomyomas is identified in the fetus during fetal morphology.

As specific features of the case, we could observe the pre-natal diagnosis of tumor formation during fetal morphology and even though tuberous sclerosis was with dominant autosomal transmission, no family members had skin changes or heart tumors, raising suspicion of a de novo gene mutation. However, to support this aspect genetic testing is recommended.

CAUSES OF DEATH IN PATIENTS WITH STAGE 0-II BREAST CANCER (Abstract): **Aim**: To analyze the main causes of death in patients with stage 0-II breast cancer who undergo breast conserving surgery or radical mastectomy, and to establish the role of imaging surveillance protocols following breast cancer treatment. **Material and methods:** We conducted a retrospective medical record review between January 2005 and December 2012, when breast cancer was the primary cause of death for 113 inpatients. All patients were admitted to the Oncology Clinic of the Iasi Regional Cancer Institute (IRCI), Romania. Patients were stratified by clinical stage 0, I and II, of which 33 (29.2%) patients were managed by breast conservation therapy and 80 (70.8%) underwent radical mastectomy. From the patient medical records all diagnostic imaging studies performed (ultrasound, radiography and computed tomography) were identified and analyzed according to a standard protocol for imaging the postoperative breast. **Results:** Bone, liver, lung, lymph nodes and local-regional recurrence were the most common sites for metastasis, while the most frequent cause of death were metastases to the liver, pleura, lung and brain. The time interval between recurrence and death ranged from 0-24 years among patients with one type of metastasis, and decreased to 0-3 years since the last recurrence for patients with multiple metastases. **Conclusions:** The current imaging protocol for monitoring the postoperative breast could be optimized to improve the prognosis and quality of life in patients with stage 0-II breast cancer. **Keywords**: BREAST CANCER, METASTASES, IMAGING PROTOCOL.

The main cause of death for women in Europe is breast cancer (1, 2). Metastases to the liver, pleura, lung and brain, diagnosed by clinical and imaging protocols, are most often responsible for patient death (3). Diagnoses of local recurrence or distant metastases in infra clinic stages allow immediate therapeutic decision making in order to improve the quality of life. In this context, the current imaging surveillance protocols following breast cancer treatment are aimed to be improved based on internationally agreed guidelines proposed by the European Society for Medical Oncology (ESMO) (4), St. Gallen Consensus Conference, Advanced Breast Cancer Consensus Conference (ABC), the German Gynecological Oncology Working Group (AGO), and National Comprehensive Cancer Network (NCCN).

The objectives of this study were: to assess the risk of local recurrence and death after breast cancer surgery; to investigate the benefits and limitations of imaging

studies in detecting local recurrence and distant metastases, and to improve the current imaging surveillance protocol following breast cancer treatment.

MATERIAL AND METHODS

We conducted a retrospective medical record review between January 2005 and December 2012, when breast cancer was the primary cause of death for 113 in patients admitted to the IRCI Oncology Clinic.

Breast cancer patients were stratified according to clinical staging at the time of diagnosis into stage 0, I and II. All patients had undergone breast surgery between January 1983 and December 2011, of which 33 (29.2%) patients were managed by breast conservation therapy and 80 (70.8%) underwent radical mastectomy.

Data drawn from patient medical records were compared using multiple regression analysis, regression coefficient, frequency distribution, chi-square test and Pearson's product-moment r ($-1 < r < 1$, the more closely the two variables are related, $r = 0$, there is no relationship between the variables). A P value of less than 0.05 was considered statistically significant. All statistical tests were performed with the Statistical Package for the Social Sciences (SPSS for Windows, Version 16.0. Chicago, IL, USA).

RESULTS

Of the 113 patients included in the study, 49 (43.4%) patients died of breast cancer-related causes and 64 (56.6%) patients had other causes of death (cardiac pathology, stroke, colon, stomach, pancreas and ovary neoplasms). Deaths resulting from breast cancer were due to local recurrence or distant metastases. The most common types of recurrence were bone metastases - 40 (35.4%) patients, liver metastases - 24 (21.2%) patients, lung metastases - 22 (19.5%) patients, local recurrence - 20 (17.7%) patients, and lymph node metastases - 18 (15.9%) patients. Most of the recurrences occurred within 3 years following the surgery. The mean survival time from recurrence to death ranged from 0.95 years (in patients with brain metastases) to 5.73 years (patients with local recurrence) (tab. I).

TABLE I

Case distribution by type of recurrence, minimum, maximum and mean survival time from recurrence to death

Type	Patients (%)	Minimum survival time (years) from recurrence to death	Maximum survival time (years) from recurrence to death	Mean survival time (years) from recurrence to death
Local recurrence	20 (17.7)	<1	24	6
Bone metastases	40 (35.4)	<1	10	3
Liver metastases	24 (21.2)	<1	8	2
Lung metastases	22 (19.5)	<1	5	1
Lymph node metastases	18 (15.9)	<1	11	3
Pleural metastases	12 (10.6)	<1	3	1
Brain metastases	11 (9.7)	<1	5	1
Skin metastases	9 (8)	<1	8	2
Peritoneal metastases	2 (1.7)	1	2	2

Of the 33 patients treated with breast conserving surgery, 11 (33.3%) patients had no recurrence and 22 (66.6%) patients had local recurrence or single/multiple organ metastases. Of the 22 patients with local recurrence or distant metastases in 17 (77.2%) the cause of death was breast cancer.

Of the 80 patients treated with radical mastectomy, 22 (27.5%) patients had no recurrence, and 58 (72.5%) patients had local recurrence or single/multiple organ metastases. Of the 58 patients with local recurrence or single/multiple organ metastases, 34 (58.6%) patients had breast cancer as the cause of death.

Comparative evaluation of local recurrence and distant metastases in breast cancer patients treated with breast conserving surgery or radical mastectomy showed that bone, liver, pleural and skin metastases were diagnosed in similar frequencies. Local recurrence, lymph node and brain metastases were more frequently observed in patients treated with breast conserving surgery. Metastatic spread to the lungs was significantly more frequent in patients treated with radical mastectomy.

Regardless of breast cancer surgery type, lung, pleural, liver and brain metastases were causes of death in breast cancer patients ($p<0.0001$). Pearson's product-moment correlation coefficient showed a significant negative correlation between mean survival time from recurrence to death and the presence of lung (r= -0,562), pleural (r= -0,394), liver (r= -0,506) and brain (r= -0,375) metastases.

Imaging methods used to diagnose recurrence /distant metastases were:

- chest CT ± chest radiograph, for the assessment of lung and pleural metastases;
- abdominal ultrasound ± CT scan for the detection of liver metastases;
- CT brain ± MRI for the detection of brain metastases.

DISCUSSION

In this study group we found that the most common sites of secondary relapse include the bone, liver, lung, and local lymph nodes. Leading causes of breast cancer death were liver, pleural, lung and brain metastases (5-9). While breast cancer patients with bone metastases and local recurrence had the longest survival interval (10 years for bone metastases and 24 years for local recurrence), the most aggressive lesions were brain metastases that caused death within the first 2 years after diagnosis (fig. 1).

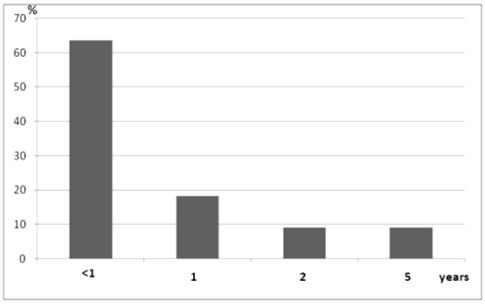

Fig. 1. Time interval from the diagnosis of brain metastases diagnosis to death in breast cancer patients

Patient survival was significantly influenced by relapses. We found that in patients with one metastatic lesion death occurred within 24 years from the time of their diagnosis, while in patients with two or more metastatic lesions death occurred within 3 years after the last recurrence.

All patients included in this study were monitored with different imaging tests at different times. For the diagnosis of lung and pleural metastases chest X-rays were

performed each year. When a clinical suspicion of lung or pleural metastasis was raised, thoracic CT was performed. It is noteworthy that metastatic lesions less than 5 mm in diameter are often not visible on standard chest X-rays (10). Hence, the necessity to include thoracic CT in the imaging surveillance protocols. For the diagnosis of liver metastases abdominal ultrasound at various time intervals (every 6 months or annually) was performed, and in doubtful cases an abdominal CT scan. The study showed that liver metastases occurred in the first 3 years after surgery, so it is appropriate to perform an abdominal ultrasound every 6 months during the first three years after surgery, then yearly. It was also noted that homogeneous ultrasound appearance of the liver does not exclude the presence of secondary lesions (11). The introduction of abdominal CT scans in imaging surveillance protocols for breast cancer patients could diagnose the liver metastases at infra clinic stage. For the diagnosis of brain metastases when clinical suspicion was raised, a cranial CT scan was indicated. In 3 of the 11 cases with brain metastases, brain MRI was indicated to establish the uniqueness of the lesion. Surgical treatment of brain metastases was indicated only if the lesion was unique and had an easily approachable location (12, 13). MRI imaging remains decisive in patients with brain metastases, which can be treated surgically.

CONCLUSIONS

In our study, the most common causes of death in breast cancer patients treated with breast conserving surgery or radical mastectomy were metastases to the liver, pleura, lung and brain. Optimizing current imaging surveillance protocols in patients surgically treated for breast cancer by using ultrasound, computed tomography and MRI can improve the quality of remaining life.

EMULSIFYING AND ANTIOXIDANT PROPERTIES OF APPLE AND GRAPE TANNINS

Preparation of an emulsion requires amphiphilic compounds that can stabilize it. The emulsions are unstable due to the surface tension between water and oil which prevents the increase of the interfacial area. Moreover, the stabilizing agents are needed to control the two competing (attracting and repulsive) forces that occur in the preparation process. Another problem would be the oxidation of lipids which are added in an emulsified system. Therefore, compounds with both stabilizing and antioxidant properties are needed. Tannins are a class of polyphenols that are widely spread in nature. Figueroa-Espinoza *et al*. studied the properties of catechin, apple and grape seed tannins, as well as their stabilizing and antioxidant capacity. They used catechin and tannin fractions isolated from grape seeds (*Vitis vinifera*, var. Shiraz) and apples (*Malus sylvestris*, var. Kermerrien). The degree of polymerization of tannin fractions was studied by HPLC after depolymerization. The antioxidant properties were evaluated using the conjugated autoxidizable triene method. The oil in water emulsions stabilized with tannins were compared with the emulsions obtained using polyvinylalcohol (PVA) and polyoxyethylene hydrogenated castor oil. The results showed that, in certain conditions, oxidized tannins provide an emulsion stability comparable to that of PVA. Furthermore, grape tannins showed higher antioxidant effects in comparison with the apple tannins. Therefore, oxidized tannins could be used as an alternative source of antioxidant emulsifiers (Figueroa-Espinoza MC, Zafimahova A, Maldonado Alvarado PG, Dubreucq E, Poncet-Legrand C. Grape seed and apple tannins: Emulsifying and antioxidant properties. *Food Chem* 2015; 178: 38-44).

SMOKING CESSATION, PULMONARY REHABILITATION AND QUALITY OF LIFE AT SMOKERS WITH COPD (Abstract): **Aim** was to compare the quality of life (QoL) at the smokers with COPD who quit smoking and have completed a pulmonary rehabilitation program with those who received usual treatment. **Material and Methods**: 437 smokers with COPD stages II and III were counseled and treated to smoking cessation and completed COPD Assessment Test (CAT) at the beginning and at the end of 12 weeks of treatment. 113 patients were enrolled in a 12 weeks supervised pulmonary rehabilitation program (PR group) and 324 smokers received usual treatment for COPD and were monitored for 12 weeks (non-PR group). The initial HbCO > 2%, and every patient completed an initial CAT. **Results:** Initially, CAT scores varied between 26 and 38. At the end of the period, CAT scores in the PR group were between 7 and 16 and in the non-PR group CAT scores were between 20 and 26, and additionally the smoking cessation failure at an important number of non-PR members (45.98%) (in PR group, 16.81%). There were reported as well higher rates of long-term abstinence in the adherent patients to PR than the other group. **Conclusions**: COPD smokers who completed the PR presented important QoL improvements, better CAT score than COPD smokers usually treated. A better PR adherence seems to be related with higher rates of sustained long term abstinence. **Keywords:** COPD, SMOKING CESSATION, PULMONARY REHABILITATION, CAT.

Smokers included in pulmonary rehabilitation (PR) is an often debate, considering PR a real aid to smoking cessation and improving the quality of smokers life.

PR is an integral part of the clinical management and health maintenance of those patients with chronic respiratory disease who remain symptomatic or continue to have decreased function despite standard medical treatment. PR aims to reduce symptoms, decrease disability, increase participation in physical and social activities, and improve the overall quality of life (QoL) for patients with chronic respiratory disease (1, 2, 3, 4, 5, 6).

The COPD Assessment Test (CAT) is a new questionnaire for people with Chronic Obstructive Pulmonary Disease (COPD). It's designed to measure the impact of the condition on a person's life, and how this

changes over time. The CAT is very simple to administer, and aims to help doctors and nurses better manage a patient's COPD. The CAT is a short, simple and validated assessment, which measures the impact of COPD on a patient's life in an objective manner (7, 8).

The objective of this study was to compare the improvement of quality of life, evaluated through CAT, between smokers with COPD who completed a PR program complementary of the smoking cessation treatment and those who received usual treatment.

MATERIAL AND METHODS

Data were obtained from the database of Smoking Cessation Center, Rehabilitation Clinical Hospital, Iasi, Romania.

Inclusion criteria were:

1) evidence of COPD according to GOLD standards (2010) (9);

2) an initial HbCO > 2%, that suggests active smoking status (10);

3) an initial COPD Assessment Test (CAT) completed by every patient.

From 437 smokers who presented at the Smoking Cessation Center between January 1 and September 1, 2011, were diagnosed with COPD stages II and III (GOLD 2010), only 113 patients (25.8%) were enrolled in a 12 weeks supervised PR program, complementary the smoking cessation treatment (PR group), and 324 smokers

74.1% received usual treatment for COPD in addition the treatment for stop smoking, monitored as well for 12 weeks (non-PR group). All patients completed the CAT questionnaire at the beginning and at the end of the determined period.

The CAT has eight items. Patients read the two statements for each item, which describe the best and worst scenario, and decide where on the scale (0-5) they fit. This system was chosen because it is reliable and simple to use. Scores for each of the 8 items are summed to give single, final score (minimum 0, maximum 40) – this is a measure of the overall impact of a patient's condition on their life.

Scores for the individual items within the questionnaire will provide insight into the relative influence that the different components of COPD have on its overall impact on a patient's life – thus, they will highlight problematic areas, which can be explored further during consultation and ultimately addressed through intervention.

Current management guidelines – such as those produced by the National Institute of Health and Clinical Excellence (NICE) (11) and the Global Initiative for Chronic Obstructive Lung Disease (GOLD) – emphasize the need for regular and effective patient monitoring and assessment. The CAT has been developed in line with the goals of these guidelines, with the aim of making these tasks easier and less time-consuming.

The data collected were analyzed in a specific program for statistical analysis (Statistical Package for Social Sciences ™-*SPSS 17.0*).

RESULTS AND DISCUSSION

PR group COPD subjects mean aged 59.02 +/- 11.424 (lim. 40-86 years old) were classified in stage II (n=50) and COPD stage III (n=63). Non-PR group COPD subjects, mean aged 67.19 +/- 10.45 (lim. 42-88) were classified in stage II (n=177) and III (n=147).

Initially, CAT mean scores of smokers with COPD were 26.84 in stage II and 30.98 in stage III and finally decreased to 10.32 and 13.95. At the end of the 12

weeks period, the CAT scores variations in the PR group were between 6-16 in COPD II patients and 7-16 in COPD III ones, comparing to the non-PR group, where CAT scores shown little improvements since the beginning of the treatment, with values between 20-26 (fig. 1), additionally to smoking cessation failure at an important number of non-PR members (45.98%) than the PR group (16.81%). There were reported as well higher rates of short and long-term abstinence at the adherent patients to PR than the other group.

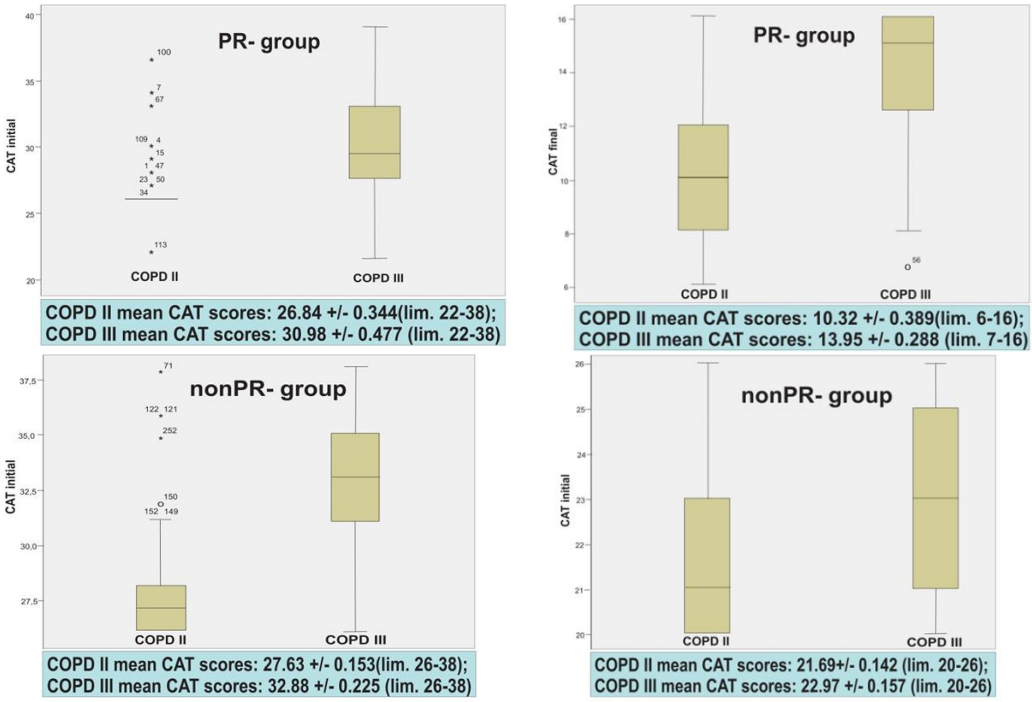

Fig. 1. CAT scores distribution by COPD stages in PR group and non-PR group

CONCLUSIONS

Although current smokers are often expected to have a small PR adherence even they intend to stop smoking, COPD smokers who completed the PR presented important QoL improvements, better CAT score than COPD smokers usually treated. Moreover, a better PR adherence seems to be related with higher rates of sustained long term abstinence.

POLIO PUZZLE AT THE BEGINNING OF 2015

Polio eradication is a very expensive campaign since 1988. In January, Ministers of Health worldwide convened at WHO's Executive Board meeting, to set global public health policies. Among other topics, representatives reviewed the current polio epidemiology and global preparedness plans for the phased removal of oral polio vaccines. The first wild poliovirus type 1 (WPV1) case of 2015 is reported this week, from Pakistan. The case had onset of paralysis on 3 January, from Khyber Pakhtunkhwa. A total number of 6 cases of polio with wild virus were confirmed in Pakistan until 4 February 2015. Afghanistan: no new WPV1 cases have been reported in the past weeks and the most recent case had onset of paralysis on 4 December 2014. Nigeria's total WPV1 case count for 2014 remains 6, compared to 53 in 2013. In Nigeria, the Expert Review Committee on Polio Eradication and Routine Immunization met last month to discuss aggressive strategies to urgently eradicate both wild- and vaccine-derived polioviruses in the country as rapidly as possible. National Immunization Days NIDs are planned in Cameroon in January using trivalent oral polio vaccine (OPV) and in Cameroon, Chad, and Gabon in February using bivalent OPV. Subnational Immunization Days SNIDs are planned in the Central African Republic in February and in Angola, Cameroon, the Central African Republic and the Democratic Republic of the Congo in March. The total number of cases that were reported in the Horn of Africa in 2014 was 6: 1 WPV1 in Ethiopia and 5 WPV1s in Somalia. Three cases of WPV1 were reported in the Middle East in 2014 2 in Iraq and 1 in Syria. Even as polio programme staff across West Africa support efforts to control the Ebola outbreak affecting the region, efforts are being made in those countries not affected by Ebola to vaccinate children against polio to create a buffer zone surrounding the Ebola affected countries. The Ebola crisis in western Africa continues to have an impact on the implementation of polio eradication activities in Liberia, Guinea and Sierra Leone. The Polio Eradication and Endgame Strategic Plan 2013–2018 is a comprehensive, long-term strategy that addresses what is needed to deliver a polio-free world by 2018. (WHO. Global polio eradication initiative, 2015).

RARE PEDIATRIC CUTANEOUS T-CELL LYMPHOMA

RARE PEDIATRIC CUTANEOUS T-CELL LYMPHOMA (Abstract): We describe a rare case of an adolescent with T-cell cutaneous lymphoma, having a history of intense pruriginous, erythematous and hyperpigmented skin lesions. Several considerations regarding diagnostic work-up and treatment must be emphasized. Erythematous, pruritic patches, unresponsive to common topical/general treatment should raise the suspicion of more serious immuno-allergic or neoplastic conditions, among which, cutaneous lymphoma could be a rare, but a realistic possibility in pediatric field. Long term follow-up by a pediatric haemato-oncologist and dermatologist team is mandatory for these patients. **Keywords:** CUTANEOUS LYMPHOMA, CHILD, PARAPSORIASIS.

In pediatric oncology Non-Hodgkin's Lymphoma is the third most common solid tumor, and constitute 5-7% of all malignancies, most often located in abdominal and thoracic regions. However, Non-Hodgkin lymphomas may have atypical primary presentations like otorhinolaryngology (1), central nervous system (CNS) or skin. Cutaneous T-cell lymphoma (CTCL) is a non-Hodgkin lymphoma that commonly occurs in elderly individuals (2,3,4,5). It is characterized by skin infiltration of malignant T lymphocytes. Mycosis fungoides (MF) is a subtype of CTCL while Sézary syndrome is its leukemic variant. The incidence varies among different age groups, with only 0.5 - 5% of cases occurring before 20 years old (3). The wide variety of clinical features and its similarities with other dermatoses may delay the diagnosis in early stages of MF. An indolent course is noticed in children and adolescents diagnosed with MF restricted to skin involvement (5). These patients require a multidisciplinary approach-pediatric haemato-oncologists, pathologists and dermatologists to improve their outcome.

CASE REPORT

We report the case of an adolescent girl who presented with a 5-months history of generalized body patches. The lesions were highly pruriginous, with mixed, erythematous and hyperpigmented regions of different sizes and shapes, with an initial chest and abdomen concentration, and a subsequent diffusion towards the upper and low-

er limbs. A cutaneous tumor of 5 cm below the right costal edge noticed. (fig. 1). Associated inguinal lymphadenopathy was observed. The patient denied drug abuse and no history of exposure to chemicals or radiation could be found.

No hepatosplenomegaly, intraoral lesions or arthralgia were found.

Fig. 1. Erythematous patches on the trunk and abdomen, erythematous plaque on the abdomen

Laboratory tests showed peripheral blood eosinophilia, with no other abnormalities. Antibodies against Cytomegalovirus, Epstein Barr virus, Toxoplasma were negative. Screening for B, C hepatitis B and C viruses, HIV, EBV, and CMV were performed for differential diagnosis of skin lesions and confirmation of chronic hepatitis and hepatic neoplasms (4).

Biopsy samples from skin lesions, lymph nodes and cutaneous tumor and subsequent histopathological and immunohistochemical examination were performed. Both skin and tumor biopsy revealed the presence of atypical epidermotropic lymphoid infiltrate with cerebriform nuclei extend into the dermis, suggestive for Mycosis fungoides (fig. 2). Also, small plaque parapsoriasis was present in the skin lesions. Lymph node biopsy revealed reactive lymphadenitis. The biopsy samples were sent to Timisoara County Emergency Clinical Hospital for further investigations. The immunohistochemistry analysis revealed positive CD2, CD3, CD4, CD5, CD7, CD8 markers and negative CD20, CD30 markers in the atypical lymphocytes from skin and tumor samples, confirming the diagnosis of MF (fig. 3).

Computed tomography of the neck, chest, abdomen and pelvis showed multiple enlarged lymph nodes in the cervical chain, axillary region (measuring up to 2.62 cm), mesentery (measuring up to 1.05 cm) and in the inguinal region (measuring up to 1.82 cm).

The bone marrow aspiration showed normal cellularity at different stages of maturation. *Clinical, laboratory and histopathological* findings established the diagnosis of Mycosis Fungoides, T3N0M0B0 - tumor stage, IIB, according to International Society for Cutaneous Lymphomas/European Organization for Research and Treatment of Cancer (ISCL/EORTC) revision to the staging of MF and Sezary Syndrome (8).

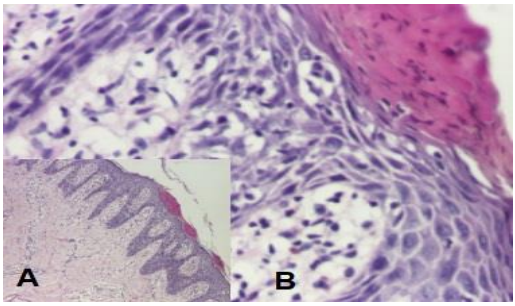

Fig. 2. A) Infiltrate into the epidermis and dermis (^{x}40 HE stains);
B) Infiltrate with abnormal cells with cerebriform nuclei, epidermotropic infiltrations of malignant cells (^{x}200 HE stains).

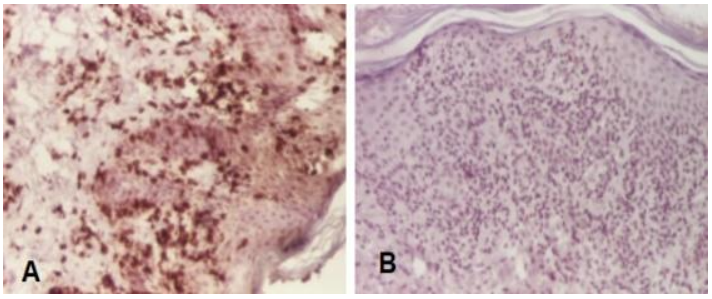

Fig. 3. A) Immunostaining - Abnormal cells positive for CD3(^{x}100);
B) Immunostaining - Abnormal cells negative for CD20 (^{x}100)

An initial regimen treatment with moderate potency topical steroids concomitant with narrowband ultraviolet B (NB-UVB) were used, followed-up by chemotherapy - cyclophosphamide, doxorubicin, vincristine and prednisone (regimen CHOP)-12 cycles, given in 21 days interval, and narrowband ultraviolet B-10 phototherapy sessions. CHOP chemotherapy sequence consisted in: Prednisone 100 mg PO daily Days 1 to 5, Doxorubicin 50 mg /m² IV Day 1, Vincristine 1.4 mg /m² IV (max 2 mg) Day 1, Cyclophosphamide 750 mg /m² IV Day 1.

The computed tomography and PET-CT were performed at the end of the treatment and showed no abnormalities. We noted a partial clinical response with the disappearance of pruritus and improvement of the skin lesions.

DISCUSSION

According to our previous experience (9, 10). pediatric neoplastic diseases may include some uncommon type of malignancies, requiring different confirmation procedures within the diagnosis process.

CTCL are quite rare among children with MF being a T-cell lymphoproliferative disorder and the major subtype of CTCL (2, 3). Data on clinical features, management, treatment response, disease progression in children are limited. MF is difficult to be distinguished from other entities in early stages due to its clinical polymorphism, mimicking benign skin disorders, that frequently occurs in pediatric age, such as eczema, atopic dermatitis, pityriasis, psoriasis. Therefore, consequently multiple biopsies may be necessary for

an accurate diagnosis (11, 12, 13).

In our case, the diagnosis of MF was suggested by histological and immunostaining parameters. Also, the association with small plaque parapsoriasis was observed in our patient.

Parapsoriasis manifests as large plaque and small plaque parapsoriasis (SPP). Both are caused by T-cell infiltration in the skin. If large plaque parapsoriasis is the earliest stage of CTCL (14,15), SPP is a benign form (16), but there were reported cases of progression to MF in adult population (17).

Our patient was diagnosed in an advanced stage-tumor stage IIB according to International Society for Cutaneous Lymphomas/European Organization for Research and Treatment of Cancer revision to the staging of MF and Sezary Syndrome (8).

Topical and systemic corticosteroids are used for treating advanced stages of MF. Systemic chemotherapy along with phototherapy is the most useful treatment schemes for advanced stages (4,18,19). In our case, no hypertension occurred, although it is known that this treatment regimen is prone to such complication (20, 21, 22). One should consider early diagnosis, fast and effective communication with stakeholders, as well as reflection upon the moral values when life is at stake, to a good prognosis (23, 24, 25, 26). Despite the several therapies reported, none of them is well-defined for children and adolescents. Our patient completed twelve cycles of systemic chemotherapy and narrowband ultraviolet B. Currently she is treated only with topical corticosteroids. Follow-up period for our patient is 2 years. She didn't develop so far, any complication or disease progression, but still has an inferiority complex about her aesthetic look.

CONCLUSIONS

We reported a rare case of juvenile-onset of MF. Long follow-up period is needed for our patient. Further studies are required for a better understanding of the outcome and prognostic implications of MF in pediatric age.

THE CORRELATION BETWEEN THE ANKLE-BRACHIAL INDEX AND THE METABOLIC SYNDROME (Abstract): On a global scale, the cardiovascular diseases constitute the prime factor of death and invalidity. The premature mortality percentage caused by these varies from 4% in high developed countries to 40% in underdeveloped countries. Atherosclerosis is the most important etiological factor. The presence of various degrees of atherosclerosis in a certain vascular area (in our case, the lower limb arteries), increases the probability of affecting other areas as well (coronary, cerebral, renal, mesenteric arteries). **Aim:** The evaluation and description of the correlations between the ankle-brachial index levels and the cardiovascular risk factors, taken individually or as part of the metabolic syndrome. **Material and method**: The values of the ankle-brachial index were divided in normal and abnormal. The evaluated cardiovascular risk factors were: age, sex, arterial hypertension, obesity, smoking, high levels of cholesterol and basal glucose, low levels of HDL-cholesterol. **Results**: There were significant statistical differences between the normal ankle-brachial index lot and the one with abnormal values, specifically in patients with diabetes mellitus and metabolic syndrome. More so, the study demonstrates that the ankle-brachial index is considerably smaller in patients with metabolic syndrome. **Conclusions:** The simple measurement of the afore mentioned index, as a atherosclerosis marker for the lower limb arteries, represents an independent prediction over the metabolic syndrome and the conventional risk factors, in the development of the cardiovascular diseases. The routine measurement of this parameter in medical practice might imply the early diagnosis of high risk manifested cardiovascular disease patients. **Keywords**: ANKLE-BRACHIAL INDEX, METABOLIC SYNDROME, CARDIOVASCULAR RISK FACTORS

The ankle-brachial index (ABI) is defined as the ratio between the systolic blood pressure, measured on ankle level, and the brachial level one, lying down, 5 minutes after resting.

The ratio is derived as follows: the blood pressure is measured on both arms, and the highest value is considered; then it is measured in the pedis and tibial bilateral posterior arteries (using a sphygmomanometer and a Doppler instrument), selecting the highest value as well. From the resulted two values of the ratio, the lowest value is further considered (1). This technique is maneuverable, non-invasive and reliable. It is applied on a large scale in medical practice to confirm the diagnosis and severity of the peripheral arterial disease (2). More

so, ABI is an indicator of generalized atherosclerosis, as the literature associates low values with an increased rate of coronary and cerebrovascular damage, as well as with the presence of numerous cardiovascular risk factors, that suggest the independent nature of it predicting cardiovascular events (3).

The metabolic syndrome, heterogeneous entity considering the gender differentiation, is currently defined, as the association of at least 3 out of 5 criteria, each with its own established reference values (4).

MATERIAL AND METHODS

A retrospective observational study was performed on 189 patients hospitalized in the Cardiovascular Rehabilitation Clinic of the Clinical Rehabilitation Hospital Iasi, between September 2011 and April 2012 (7 months).

The patients were divided in two batches, based on the values of ABI: first batch, with abnormal values (ABI $\leq$ 0.9) and the latter, with normal values (ABI between 0.9 and 1.4) (5).

Subjects with ABI values higher than 1.4 were excluded from the study, due to an increased level of errors determined by the arterial stiffness (6). Other exclusion criteria were: secondary arterial hypertension, severe chronic renal disease (dialyzed patients), major cardiovascular events (myocardial infarction, stroke, and chronic heart failure, myocardial or peripheral revascularization) (7).

RESULTS AND DISCUSSION

The gender repartition varied: 74.1% (140) male subjects, and 25.9% (49) female. Patients' age ranged from 37 up to 83 years. In addition, 59.8% (113) came from urban areas, while the remaining 40.2% (76) resided in rural areas. No statistic age difference was observed amongst the study group, between the two genders (p=0.606) (fig. 1).

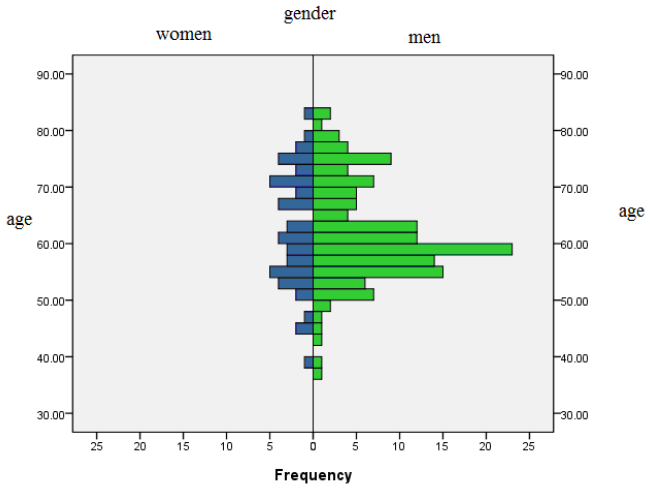

Fig. 1. Age over sex distribution

The maximum systolic blood pressure level, depending on the ABI values, registered the following results:

- ABI $\leq$ 0.9 batch, values between 120-290 mmHg, with an average value of 180 mmHg;

- ABI > 0.9 batch, values between 135-260 mmHg, with an average value of 190 mmHg.

There were no significant differences between the two batches (8) (fig. 2).

The statistical analysis of the cholesterol (fig. 3) and HDL-cholesterol levels (fig. 4) depending on the ABI values revealed the following:

- normal distribution of cholesterol and HDL-cholesterol levels on ABI ≤ 0.9 subjects (107-345 mg/dl, with an average of 187 mg/dl for cholesterol and 19-82 mg/dl, with an average of 40 mg/dl for HDL-cholesterol);

- non normal distribution on ABI > 0.9 patients (110-351 mg/dl, with an average of 193 mg/dl, and 27-80 mg/dl, with an average of 41 mg/dl respectively).

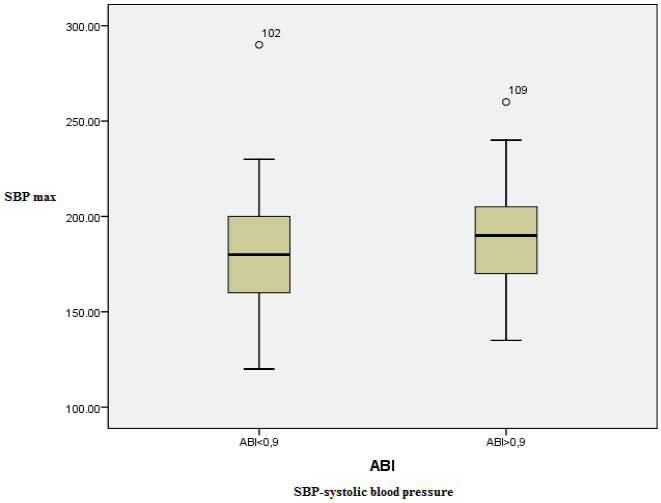

Fig. 2. The correlation between ABI and SBPmax

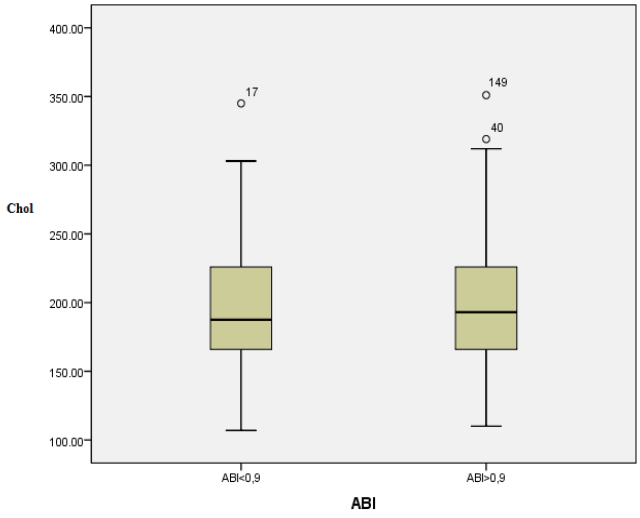

Fig. 3. ABI and cholesterol levels

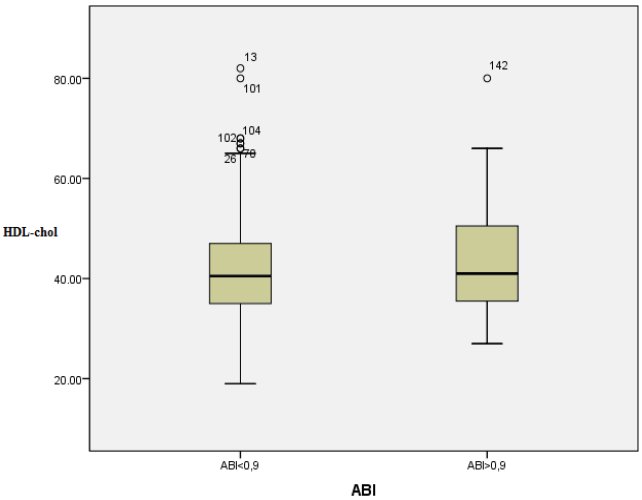

Fig. 4. ABI and HDL-cholesterol levels

Again no significant differences were observed (9).

In ABI ≤ 0.9 batch, there were 26 patients with diabetes mellitus, compared to 43 from the second batch, with a significant statistical difference between the two (p=0.049) (10).

The analysis of the correlation between smoking and ABI values showed no differences (11) (fig. 5).

The study batches' average body mass index (BMI) was 29 kg/m^2, with a variation between 18 and 49 kg/m^2, without a significant difference (p=0.227) (12, 13) (fig. 6).

In the ABI ≤ 0.9 batch, there were 16 patients with left ventricular hypertrophy (LVH), compared with 20 patients from the second batch, with no significant statistical difference between the two (p=0.714).

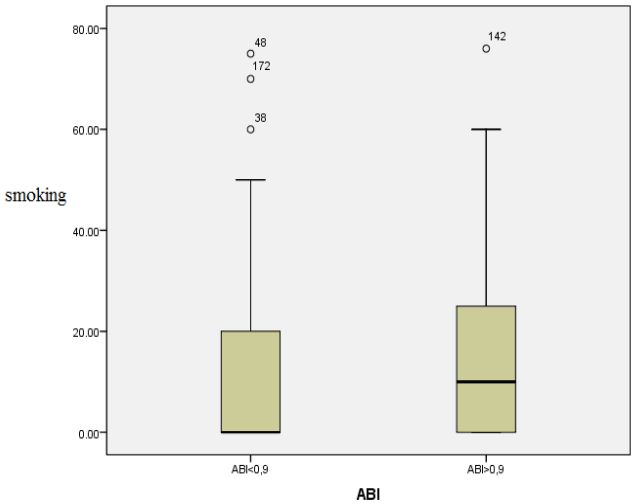

Fig. 5. The correlation between

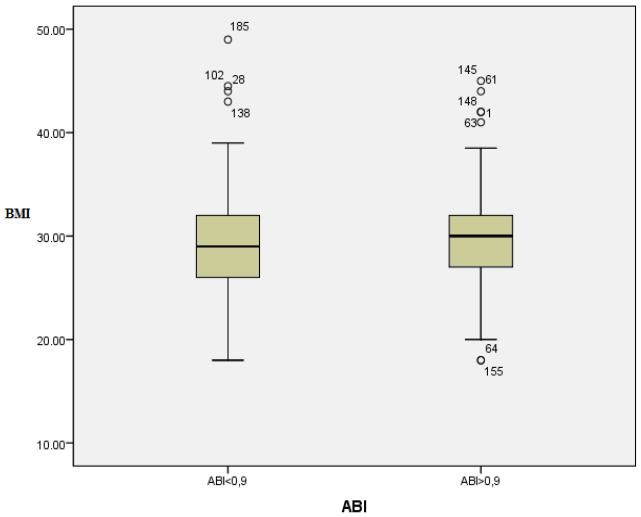

Fig. 6. ABI and BMI smoking and ABI

Regarding the main objective of the present study, establishing a correlation between the ABI values and the presence of the metabolic syndrome, it was demonstrated that the distribution of the latter was non-normal for both batches; the metabolic syndrome was present on 49 patients with ABI ≤ 0.9 and 32 patients with ABI > 0.9, with a significant statistical difference (p=0.003); moreover the ABI values were considerably lower on patients with metabolic syndrome (14) (fig. 7).

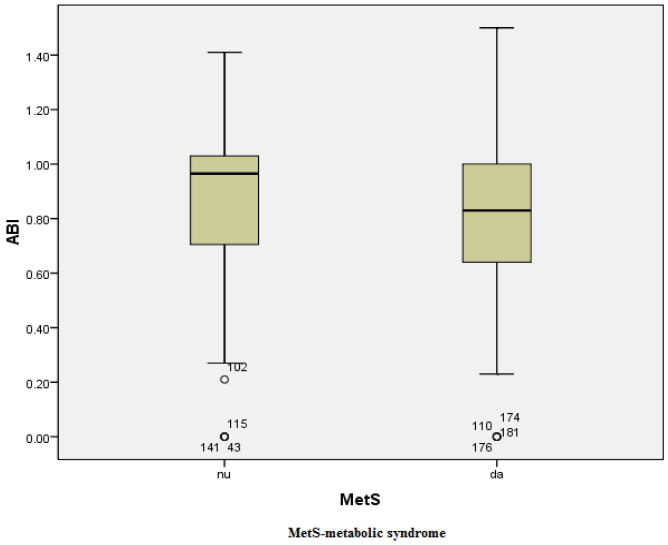

Fig. 7. ABI and the metabolic syndrome

CONCLUSIONS

This study strengthens the literature results and demonstrates that the low ABI values (as a marker for atherosclerosis in lower limbs arteries) represent an independent predictor in relation with the metabolic syndrome and conventional risk factors, in the development of cardiovascular disease. Introducing the routine measurement of this parameter in medical practice might imply the early diagnosis of high risk manifested cardiovascular disease patients.

SNEDDON SYNDROME: RARE DISEASE OR UNDER DIAGNOSED CLINICAL ENTITY? REVIEW OF THE LITERATURE RELATED TO A CLINICAL CASE (Abstract). Sneddon syndrome is defined by the association of livedo racemosa and recurrent cerebrovascular ischemic lesions. The annual incidence is 4/1,000,000. This syndrome particularly affects young women, some reports suggesting a family predisposition. It is a chronic, progressive, arterio-occlusive disease of unknown etiology that involves small and medium-sized arteries. It is usually associated with antiphospholipid antibodies. We report the case of a female patient with Sneddon syndrome with significant family history, personal history of stroke, epilepsy, migraine, cardiovascular involvement, three miscarriages, cognitive decline, noncompliant to therapy, in the absence of antiphospholipid antibodies. This paper aims to analyze the main characteristic features and management of Sneddon syndrome by conducting a literature review related to a clinical case. **Keywords:** SNEDDON SINDROME, CEREBROVASCULAR DISORDER, LIVEDO RACEMOSA, ANTI-PHOSPHOLIPID ANTIBODIES.

Sneddon syndrome is a condition characterized by the association of livedo racemosa and ischemic strokes (especially in the middle cerebral artery territory); it was named after the British dermatologist Sneddon, the first to draw attention to this association in 1965. Sneddon syndrome affects mainly women (80%) aged 20-40 years; livedo racemosa precedes neurologic impairment and the first cerebral ischemic event usually occurs before the age of 45. The annual incidence is estimated at 4/1,000,000 but data suggest that Sneddon syndrome is under diagnosed; it has been estimated that Sneddon syndrome affects 1:2000 stroke patients and the prognosis for these patients is poor (1).

It is a chronic, progressive, non-inflammatory, arterial occlusive disease of unknown cause that affects small and medium sized arteries in the brain and skin, although there are studies that state its system-

ic nature. Cardiovascular system is the most commonly involved (hypertension, ischemic heart disease, valvular disease), but the visual system, gastro-intestinal system and kidneys may also be affected. The association with antiphospho-lipid antibodies is controversial (0-85%).

Some studies describe a significant family history in Sneddon syndrome patients, and autosomal dominant with incomplete penetrance or autosomal recessive arrays were suggested (2, 3, 4).

Sneddon syndrome is not currently regarded only as a clinical diagnosis but rather as a common clinical manifestation of different diseases. Various authors have classified the disorder in primary Sneddon syndrome (without evidence of etiological factors) and secondary (autoimmune, thromboembolic, associated with systemic lupus erythematosus, associated with antiphospholipid syndrome) (5). No treatment has proven effective for this condition.

Pathophysiology. Recent data suggest that Sneddon syndrome begins as an inflammatory, possibly immunologically-mediated disorder which develops into the migration and proliferation of smooth muscle cells in small and medium-sized arteries that result in vessel stenosis. The disease progresses in four stages: early stage (I), characterized by attachment of lymphohistiocytic cells and detachment of endothelial cells followed in stage II by total or partial occlusion of the lumen with a plug of fibrin and lymphohistiocytic cells; the plug is then replaced in stage III by proliferating subendothelial cells and stage IV is characterized by fibrosis and stenosis of the vessel (1,6).

Clinical diagnosis. Sneddon syndrome is a clinical diagnosis as there is still no specific test for it. Livedo racemosa is usually located on the limbs (100%), trunk (89%), buttocks (74%), face (15%), hands and feet (59%). Neurological manifestations occur after an ischemic stroke, usually in the middle cerebral artery territory and usually consist of hemiparesis, sensory deficits, aphasia and dysarthria, but visual field deficits and drop attacks may also occur. TIAs are common and spinal infarcts, intracerebral, subarachnoid and intraventricular hemorrhages were also reported (1).

Other neurological manifestations associated with Sneddon syndrome are headache, vertigo (the most common), chorea, epilepsy, myelopathy, migraine, hemicrania, acute encephalopathy, amnesia, internuclear ophthalmoplegia, nystag-mus, ophthalmic artery occlusion, myasthenia gravis, polyneuropathy, Raynaud syndrome (1). In almost all cases the disease advances to cognitive dysfunction, personality changes, depression and late dementia.

Impairment of other systems has been reported: cardiovascular (hypertension, valvular, aortic or mitral regurgitation usually, ischemic heart disease), ocular, gastrointestinal, renal, gynecological (miscarriages, sterility), suggesting a systemic nature of the disease (1, 7, 8).

Of the clinical manifestations, migraine and headache appear to be most strongly associated with the risk of a new stroke (9).

Laboratory exams. Recent studies support the importance of skin biopsy and cranial imaging in the diagnosis of Sneddon syndrome. Wohlrab *et al.* used a skin biopsy method that required taking a deep punch biopsy (4 mm) from the white areas, the sensitivity of the method increasing with the number of biopsies: 27% one biopsy, 53% two biopsies, and 80% with three biopsies (10). Ultrastructural and immunohistochemical investigations have shown that the migrating cells from the media contain smooth muscle actin (smooth muscle cells or myofi-

broblastic cells). Hilton and Footitt reported the main findings in the brain tissue biopsy to be small cortical infarcts associated with the occlusion of the small and medium arteries and prominent focal hyperplasia of the media in the small arteries, similar to the skin findings (1).

MRI can detect cortical and/or subcortical arterial infarcts, usually multiple, and periventricular white matter abnormalities. Diffuse cortical-subcortical atrophy has been reported in advanced stages. The results of cranial angiography are inconsistent, some studies describing various abnormalities (irregular vessel calibre, occlusion or stenosis of major cerebral vessels, medium and small vessel stenosis, large networks of fine collateral vessels and granulomatous leptomeningeal infiltration, transdural anastomoses, lobar intracerebral hemorrhage with "pseudo-angiomatosis" pattern), others did not report any abnormalities (1,11).

Stockhammer suggested using MRI and duplex sonography in detecting large vessel occlusions, while Canepari *et al*. have demonstrated a strong relation between SPECT analysis of cerebral perfusion, clinical findings, and disease progression; functional imaging associated with MRI seem to have a good sensitivity in the follow-up of these patients (11, 12, 13).

The combination of Sneddon syndrome and antiphospholipid antibodies (APAs) has been reported in quite variable percentage, ranging from 0 to 85%, most authors suggesting values of 40-50% (1). Some authors have concluded that thrombocytopenia, proteinuria, epilepsy, and mitral regurgitation occur more often in the presence of APAs associated with Sneddon syndrome, whereas livedo network appears to be broader in Sneddon syndrome without APAs. Others have found that the presence of APAs indicates a lower risk of thrombosis and a much less severe course of the disease (1, 14, 15).

Numerous other prothrombotic abnormalities have been reported: heterozygous factor V Leiden mutation, deficiency of protein Z, resistance to activated protein C, increased platelet aggregation, and increased ß-tromboglobulin, modified plasminogen activator/inhibitor ratio, familial antithrombin III deficiency, increased factor VII activity (1, 16, 17, 18, 19). Our patient tested negative for APAs, proteins C and S were normal, although bleeding and clotting parameters were modified.

Differential diagnosis. Differential diagnoses include other conditions that associate livedo racemosa and cerebrovascular events such as: APA, systemic lupus erythematosus (SLE)- it can present with livedo racemosa (11.7%), especially associated with anti-Ro antibodies, and neurological symptoms (amnesia, cognitive impairment, depression), Divry van Bogaert syndrome, thrombangiitis obliterans - reported as a rare complication of Buerger disease, is clinically similar to Sneddon syndrome.

Other differential diagnoses to be considered are polyarteritis nodosa, cholesterol emboli syndrome, livedoid vasculopathy. Rarely, livedo racemosa may be associated with: hematological abnormalities (essential thrombocythemia, polycythemia vera, pernicious anemia, DIC, cryofibrino-genemia), hyperthyroidism, rheumatoid arthritis, Sjogren's syndrome, derma-tomyositis, scleroderma, temporal arteritis, calciphylaxis in chronic dialysis patients, hyperoxaluria, atrial myxoma, post-streptococcal syndrome, borreliosis (1).

Course. The natural course of Sneddon syndrome is marked by recurrent ischemic strokes accompanied by progressive cerebral atrophy and dementia, leading to disa-

bility and a mortality of 9.5% over an observation period of 6.2 years (11).

Treatment. Due to lack of controlled trials, the management of Sneddon syndrome patients remains controversial. Corticosteroids and immunosuppressive therapy appear to be ineffective. It has been found that the presence of APAs in Sneddon syndrome may influence the management and patients with positive APA respond well to anticoagulant treatment with warfarin in high doses (20). Wohlrab *et al.* proposed a long-term triple prophylactic therapy with pro-rheological agents (prostaglandin E1), against myocyte proliferation (Captopril) and antiplatelet that led to halting disease progression over 3-5 years (1). Hannon *et al.* reported improved memory and emotional status after treatment with cyclophosphamide (21), while other authors state that intravenous thrombolysis may be effective and safe in patients with Sneddon syndrome (22); also, these patients should avoid smoking and oral estrogen contraceptives (1).

Prognosis. It seems that patients who associate APAs have a better prognosis than those without APAs, wand a better response to anticoagulant treatment. Systemic involvement, especially cardiovascular, leads to a poorer prognosis and the presence of migraine in patients with Sneddon syndrome is associated with an increased risk of stroke (9, 10). The best follow-up methods for preventing cerebrovascular ischemic lesions in patients with Sneddon syndrome seem to be the brain imaging techniques (MRI and SPECT) (13).

Although Sneddon syndrome is a clinical diagnosis, it requires multiple investigations, necessary for initial assessment of systemic involvement, prognosis and treatment plan.

CASE PRESENTATION

To illustrate the complexity of approaching such a patient we present the case of a 42-year-old woman admitted to the Department of Internal Medicine of the Iasi "Dr. C.I. Parhon" Hospital who upon admission showed uncontrolled high blood pressure values, frontal occipital headache of moderate intensity (5 p/10 on the visual analog scale), faintness, vertigo accompanied by nausea and vomiting, visual disturbances, muscle weakness and chest pain.

Fig. 1. Livedo racemosa of the left arm

Fig. 2. Livedo racemosa of the legs

Physical exam revealed skin changes characteristic for "livedo racemosa" (fig. 1, 2), visible on the thighs, arms and trunk, with onset at the age of 22 years and

trophic disorders of the legs.

Neurological exam revealed left spastic hemiparesis, left facial paresis, central motor deficit of the left limbs.

Our patient had a significant family history, a grandmother who died of stroke, a brother who suffered from stroke, the mother who had livedo reticularis and a personal history of three miscarriages, grade 3 arterial hypertension, epilepsy and migraine.

Known with neglected arterial hypertension, nonsmoker, denied use of estrogen products, our patient presented an episode of left faciobrachial motor deficit resolved within 3-4 days at the age of 34. At the age of 39 she suddenly experienced a left limb motor deficit following strenuous exercise; glucocorticoids and antiplatelet agents were administrated and the course was favorable.

The suspicion diagnoses were Sneddon syndrome, antiphospholipid antibody syndrome, and systemic lupus erythematosus; for confirming the diagnosis we performed full blood and biochemical tests, autoimmune markers, coagulation tests, heart examination (ECG, Holter, transthoracic echocardiography), CT, MRI and skin biopsy and the results were:

- Brain MRI: multiple ischemic brain lesions located in the right parietal and left occipital lobes (fig. 3) while cranial CT showed an insular frontal ischemic sequels and cerebral atrophy;
- Laboratory tests: the absence of antiphospholipid antibodies, p-ANCA and c-ANCA, ANA and anti-dsDNA antibodies were negative, protein C and S were normal, while bleeding and coagulation time were decreased (BT = 1'00 ", CT = 5'48");
- Skin biopsy: discreet perivascular lymphocytic infiltrate and bulging of vascular endothelium;
- Holter: systolic values ranged between 140-160 mm/Hg and echocardiography revealed normal heart cavities, with a LVEF = 65%.

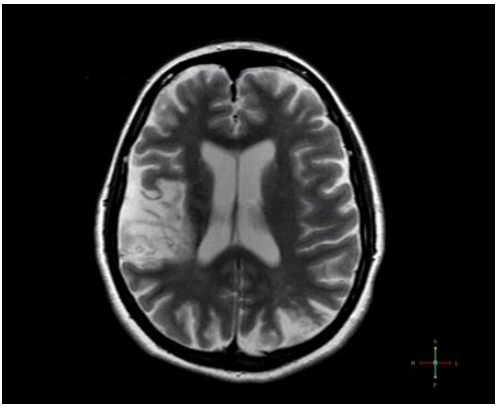

Fig. 3. MRI imaging: Ischemic lessions located in the right parietal and left occipital lobe

In our patient, a positive diagnosis of Sneddon syndrome was based on the presence of clinical symptoms (livedo racemosa, neurological and cognitive impairment), history of stroke, and brain imaging suggestive of ischemic changes accompanied by cerebral atrophy.

The most eficient and used drugs for arterial hipertension asociated with angina pectoris seems to be ß blockers and angiotensin receptor blockers II /sartans (23) and our pacient was treated with ß blocker, vasodilator, antiplatelet, oral anticoagulant and neurological treatment, resulting in halting the progression of the disease, with good blood pressure control and absence of a new cerebral ischemic event or degradation of cognitive status, but unchanged neurologic manifestations.

As our patient had a suggestive family history, personal history of two strokes, cognitive dysfunction (suggestive of an

advanced stage of disease), migraine, cardiovascular abnormalities (hypertension, angina pectoris), pro-thrombotic status (suggested by the 3 miscarriages), tested negative for APAs (usually associated with poor anticoagulant response and a more severe course of the disease) and was non-compliant, the prognosis was poor.

CONCLUSIONS

Although considered a rare disease, new studies show that Sneddon syndrome is actually an under diagnosed clinical entity and recognizing this disease is important in the management and subsequently in the outcome of these patients. Therapeutic conduct in these cases is difficult in the absence of a well-established protocol. Management of patients with Sneddon's syndrome should be multidisciplinary because morbidity is significant (recurrent stroke, cardiac ischemia, hypertension, miscarriages, cognitive impairment). The evolution is progressive; therefore the follow-up for these patients should be regularly done, both by clinical examination and by analyzing MRI, SPECT and echocardiography. In the absence of effective treatment, management of these patients involves removing known modifiable risk factors (smoking and eliminating estrogen products, cardiac ischemia, hypertension, hypercoagulability, epilepsy).

Our patient had multiple risk factors and was diagnosed with Sneddon syndrome 20 years after the first symptoms appeared. A more prompt diagnosis would have led to a more rapid initiation of appropriate treatment and as such to an improved prognosis.

DETERMINANTS OF INADEQUATE WEIGHT GAIN IN PREGNANCY. **Aim.** The aim of the study was to explore the anthropometric maternal characteristics and prenatal care as determinants of pregnancy weight gain. **Material and methods.** We conducted a cross-sectional study on a total of 400 pregnant women admitted to Cuza-Vodă Obstetrics and Gynecology Clinical Hospital, Iaşi. Information on demographic characteristics, number of prenatal visits, and education on nutrition and food changes occurring during pregnancy were recorded in a structured questionnaire. Anthropometric parameters analyzed were pregestational BMI (body mass index) and weight gain during pregnancy. **Results.** Weight gain was associated with pregestational BMI category. An increase in weight more than recommended occured more frequently in overweight (53.1%) and obese women (66.7%) ($p<0.001$). Weight gain during pregnancy was related to area of residence, age, APCU (adequate prenatal care utilization) index. The multivariate analysis identified the following variables as significant determinants of pregnancy weight gain: inadequate prenatal care, BMI and changes in diet. **Conclusions.** Pregestational BMI and changes in diet during pregnancy identified as determinants of weight gain suggests that overweight and underweight women must carefully be counseled regarding recommendations for weight gain in pregnancy. Tracking diet changes is important to ensure that a weight gain lies within the guidelines recommendations. **Keywords:** PREGESTATIONAL BMI, WEIGHT GAIN DURING PREGNANCY, PRENATAL VISITS, NUTRITIONAL EDUCATION

The main purpose of recommendations for weight gain during pregnancy is represented by a normal weight of newborns. Numerous factors can influence weight gain in pregnant women, such as: previous nutritional status, age, parity, race and dietary habits (1). Overweight is associated with an increased risk for preeclampsia, gestational diabetes and caesarean section (2, 3). The pre- and postnatal nutritional environment is important in shaping the future phenotype of the organism, influencing the risk of insulin resistance, type 2 diabetes and cardiovascular disease in adult life. The aim of the study was to explore the determinants of inadequate weight gain during pregnancy.

MATERIAL AND METHODS

We conducted a cross-sectional study on

a sample of 400 women, admitted to Cuza-Vodă Obstetrics and Gynecology Clinical Hospital, Iasi, in August-September 2010. Exclusion criteria were multiple pregnancy, patient refusal and obstetric pathology.

A standardized questionnaire provided information on age, pregestational weight, area of residence, marital status, years of formal education, parity and prenatal care utilization (date of registration, the number of medical visits to the family doctor and obstetrician). Weight and height were measured in duplicate and recorded according to the standard protocol. Prepregnancy nutritional status was classified based on BMI (body mass index), according to the World Health Organization (WHO) criteria. Weight gain during pregnancy was divided into three categories (less than 9 kg, 9-15 kg and above 15 kg) according to general practitioner guidelines (4).

Adequacy of prenatal care utilization was assessed by determining the Adequacy of Prenatal Care Utilization Index which takes into consideration the timing of prenatal care initiation and the number of prenatal visits. The index is based on ACOG (American College of Obstetricians and Gynecologists) recommendations for low risk pregnancies and has 4 categories. Inadequate prenatal care includes women who were registered after the fourth month or had less than 50% of the number of recommended visits in pregnancy. Women registered after the fourth month with a total of 50-79% of visits are included in the intermediate care category. Initiation of prenatal consultation in the first 4 months of pregnancy and a total of 80-109% of visits correspond to adequate care category. Adequate plus category refers to the initiation of prenatal consultation in the first 4 months and total medical checks of more than 110% compared to the number recommended (5).

The statistical package *SPSS 13.0* for Windows (Chicago, IL, USA) was used for data analysis. For the prediction of inadequate weight gain, multinomial logistic regression was used. Significance values of Goodness-of-Fit test were higher than 0.05, so the model was adequate. Access to data observation sheet, the mother interview and the measurements were made with the agreement of management of Cuza-Vodă Obstetrics and Gynecology Hospital, and with the approval of Science and Ethics Committee of the University of Medicine and Pharmacy ”Grigore T. Popa”- Iaşi.

RESULTS

Almost half of the participants (45.8%) were from rural areas. The mean age was 27.53 years, and 63.8% of all women were between 19 and 30 years old. Pregnancy occurred in married couples in 80.75% of cases. Primiparous women were predominant (49.5%) and also those with a second child (32.3%) (tab. I).

A proportion of 80% of women presented to the family doctor during the first trimester of pregnancy. The mean total number of medical visits during pregnancy was 9.58±4.88.Almost half of women (53.5%) had an adequate plus prenatal care level, evaluated by APCU (adequate prenatal care utilization) index, while 23% of them had inadequate care during pregnancy. A proportion of 42.3% of women received advice about nutrition in pregnancy. Only 33% declared they had no change in diet during pregnancy. Most women were advised to breastfeed their children (83.5%).

The frequency of underweight women was 11.8%, 66.6% were normal weight,

17% overweight and 4.6% were obese. Only 52.6% of women achieved a weight gain during pregnancy as recommended by the guide for general practitioners' (9-15 kg). Pregnancy weight gain was influenced by area of residence and age. The number of women with weight gain less than 9 kg was higher among those from rural areas. Pregnant women younger than 20 years old had more frequently a lower weight gain than recommended, but rarely an increase of more than 15 kg (tab. II).

TABLE I
Sociodemographic characteristics of the studied sample

		No.	**%**
Area of residence	urban	217	54,3
	rural	183	45,8
Age (years)	< 20	356	89,0
	≥ 20	44	11,0
Formal education (years of schooling)	1-4	16	4,0
	5-8	86	21,5
	9-12	162	40,5
	>12	136	34,0

	unmarried	77	19,2
Planned pregnancy	yes	359	89,8
	no	40	10,0

TABLE II
Sociodemographic characteristics related to weight gain during pregnancy

Socio-demographic characteristics		**Weight gain categories, %**			**P**
		< 9 kg	**9-15 kg**	**> 15 kg**	
Area of residence	Urban	9,3	48,6	42,1	**,001**
	Rural	17,5	57,8	24,7	
Planned pregnancy	Yes	13,5	51,1	35,3	,197
	No	6,1	66,7	27,3	
Civil status	Married	32,7	48,1	19,2	,173
	Unmarried	12,7	50,6	36,6	
Age (years)	≥20	12,0	51,3	36,7	**,021**
	< 20	20,5	64,1	15,4	
Formal education (schooling years)	< 9	11,6	51,0	37,3	,095
	≥ 9	16,7	57,8	25,6	
Parity	≤ 2	11,9	51,6	36,6	,128
	> 2	17,7	58,1	24,2	

Most of underweight women had an adequate weight gain during pregnancy. However, 39.5% had a weight gain of more than 15 kg. Women with obesity had more frequently a reduced weight gain compared to other categories, but the proportion of those with large increases in weight remained high (p=0.001) (tab. III).

Pregnant women with adequate prenatal care had a higher mean weight gain compared to those with inadequate or intermediate APCU index (p<0.001). Significant differences were seen between women with inadequate and adequate care (12.53 kg *vs.* 14.42 kg., p = 0.041) and among those with inadequate and adequate + APCU index (12.53 kg *vs.* 15.05 kg, p<0.001). Weight gain of pregnant women with adequate + APCU index was also significantly higher than the one seen in those with intermediate and adequate prenatal care (15.05 kg *vs.* 12.53 kg, p <0.001, respectively 15.05 kg *vs.* 14.42 kg, p=0.007). (fig. 1).

A weight gain under the recommendations was noticed in 20.4% of women who received advice on diet during pregnancy, compared to 25.5% of women who did not receive such information. An increase in weight greater than recommended occurred in 35.3% of women who received advice about diet, compared to 33.8% of them who have not received such advice. Weight gain within the recommendations was more common among women who received advice on nutrition during pregnancy, even if there was no statistical significance (44.3% *vs.* 40.7%, p = 0.496).

TABLE III

Weight gain during pregnancy according to pregestational BMI

Weight gain, kg	Categories of BMI, %			
	Under weight	Normal weight	Over weight	Obese
<9	4,7	5,5	12,7	33,3
9-15	55,8	60,5	54	27,8
>15	39,5	34	33,3	38,9

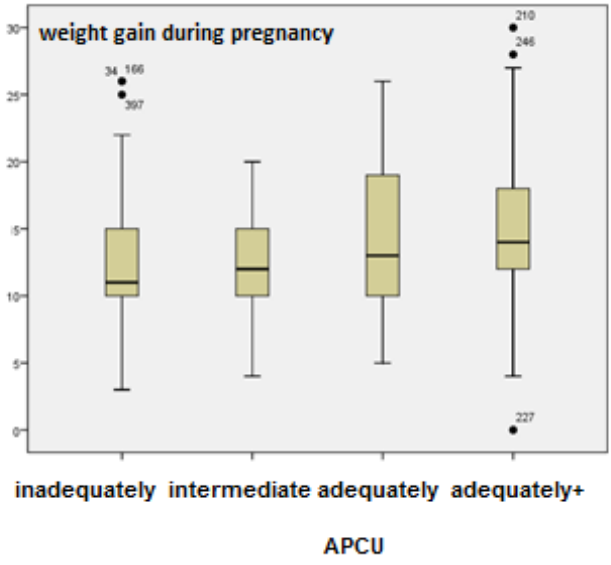

Fig. 1. Association between weight gain and APCU index

Multinomial logistic regression was performed to determine which of the following factors determinants of inadequate pregnancy weight gain are: area of residence, age, education, marital status, parity, planned pregnancy, APCU index, nutritional advice, pregestational BMI, changes in diet during pregnancy (tab IV).

b-reference category

Variables that significantly contributed to distinguish between the three categories of weight gain during pregnancy were: APCU index; pregestational BMI; changes

in diet and age. A weight gain lower than the recommended was associated with inadequate prenatal care, pregestational BMI < 18.5 kg/m^2 and normal pregestational weight. Weight gain higher than recommendations was associated with changes in diet, age less than 20 years and an intermediate value of APCU index.

DISCUSSION

Prenatal care is essential for screening and prevention of complications associated with pregnancy (6). WHO recommends initiation of prenatal care during the first 4 months of pregnancy (7). Continuity (8) and frequency of prenatal care (9) have positive effects on mother and child health. APCU index combines in a single variable two quantitative factors: gestational age, in months, at beginning of prenatal care and the number of prenatal visits during pregnancy. Because prenatal care needs to be appropriate, registration should be done during the first trimester and the number of prenatal visits should be at least nine. Although the name includes the term appropriate, the index does not refer to the content of prenatal consultation (5).

Our data show an improved addressability to general practicionner during the first trimester of pregnancy compared to previous studies. In the study conducted by IOMC "Nutritional status of pregnant women" almost 6% of women received no prenatal visit during their last pregnancy, and 68.8% of mothers were presented at the first prenatal visit during the first trimester of pregnancy (79.2% in urban and 58.5% rural) (10). The Reproductive Health Survey 2004, most women (94%) received prenatal care, and 74% were considered in the first trimester. Only 17% were considered in the second and 2% in the third trimester. In 1999 it was found that 89% of women received prenatal care (10). The self-reported weight was used in the present study. For accurately assessing this parameter it is recommended to use the self-reported weight in the first two months of pregnancy (11). However, there are studies showing that mothers declared a value that correlates with real weight (12).

Pregnancy is considered an appropriate time for promoting healthy changes in dietary habits (13). Characteristics of intervention methods, content and frequency of educational measures and socio-economic peculiarities led to discordant results of interventional studies. The impact of recommendations on weight gain during pregnancy has been shown in numerous studies, indicating that messages during prenatal consultation may influence attitudes and perceptions of pregnant women on optimal growth. The impact of recommendations on appropriate weight gain may be influenced by family and friends attitude on prenatal education (14).

In this sample, it has been observed that only 57.6% of women had an optimal weight gain. Studies in the U.S. have shown that 30-40% of pregnant women have a weight gain outside the limits recommended by the Institute of Medicine (15). Our results show that the number of prenatal visits influenced the proportion of women with optimal weight gain. Pregnant women with inadequate prenatal care had more frequently a weight gain below the recommended limits. Weight gain within the recommendations was more common among women who received advice on nutrition during pregnancy. Other studies concluded that belonging to certain ethnic groups (Hispanic), educa-

tion level, decreased pregestational BMI and the lack of nutritional advice were determinants of lower than recommended weight gain (14). Overweight, young age and multiparity had a higher weight gain than considered appropriate by the IOM (14). Weight gain above the recommended level was associated with overweight and obesity in a study conducted in Brazil (16).

CONCLUSIONS

Pregestational BMI, APCU index and changes in diet during pregnancy identified as determinants of weight gain suggests that overweight and underweight women must carefully be counciled regarding recommendations for weight gain in pregnancy. Tracking diet changes is important to ensure that a weight gain lies within the guidelines recommendations.

INFECTIOUS ENDOCARDITIS WITH FIVE LOCALISATIONS - CASE REPORTS

Alina-Costina Luca, C. Iordache
University of Medicine and Pharmacy "Grigore T. Popa" – Iaşi
Faculty of Medicine
Discipline of Pediatrics

INFECTIOUS ENDOCARDITIS WITH FIVE LOCATIONS - CASE REPORTS (Abstract) Infectious endocarditis is defined as an infection of the endocardial surface area of the heart which can include one or more cardiac valves, mural endocardium or a septal defect. We present the case of a patient, aged 8, hospitalized in Hemato-Oncology Department with pontine glioma, who was diagnosticated with infectious endocarditis with five localisations.
K**eywords**: ENDOCARDITIS, CARDIAC VALVES, SEPTAL DEFECT.

Infectious endocarditis is defined as an infection of the endocardial surface area of the heart which can include one or more cardiac valves, mural endocardium or a septal defect (1, 11). Its intracardiac effects include severe valve insufficiency which can lead to congestive cardiac insufficiency that is hard to treat and to myocardial abscesses. If it is left untreated, the infectious endocarditis is, in general, fatal (2, 6).

Endocarditis can be classified into:

• native valve endocarditis, acute and subacute;

• early and late prosthetic valve endocarditis;

• secondary endocarditis in intravenous drug users (4, 7).

Rheumatic diseases represent now less than 20% of the cases and 6% of the patients with cardiac rheumatic disease finally develop infectious endocarditis. Congenital cardiac diseases represent 15 % of the cases, with bicuspid aortic valve being the best known example (10).

Acute endocarditis is caused most frequently by *Staphilococcus aureus*, it appears on a normal valve, and is rapidly destructive, produces metastatic foci and if not treated is fatal in less than 6 weeks (5, 8). Subacute endocarditis is caused usually by viridans streptococci, it appears on valves with pre-existent injuries, it does not determine metastatic foci and, if not treated, it needs more than 6 weeks or even a year to become fatal (8,9).

Other congenital anomalies which lead to the appearance of endocarditis include ventricular septal defect, persistence arterial channel and tetralogy of Fallot. Atrial septal defect is rarely associated with infectious endocarditis. Mitral valve prolapse is the most common predisposing factor, more frequently found in young patients and is the predisposing condition in 30% of the cases of native valve endocarditis in this age group. Infectious endocarditis complicates 5% of the cases of asymmetric septal hypertrophy, which usually involves

the mitral valve (2, 3).

CASE REPORT

A 8 years and 2 months old male patient is transferred to the IVth Clinic of Hematology Oncology with signs and symptoms of acute cardio-respiratory insufficiency: generalized edema, dyspnea with orthopnea, hepatomegaly of under 4 cm below the rim, tachycardia, low blood pressure, rales on bilateral, the reason for which he is transferred to Intensive Therapy Section.

The patient at the debut of the disease at the beginning of October 2008 with headache resistant to symptomatic treatment. After a week, convergent squint of the left eye appears. The ophthalmological and neurological examination recommends correction of the squint by wearing glasses. In December 2008, mother notices balance disorders, nasal voice and discrete swallowing disorders.

CT and IRM examinations showed a cerebral edema in December 2008, and a suspicion of brainstem glioma in January 2009. Progressive deterioration of the general state, persistence of balance disorders, progressive squint and swallowing disorders imposed treatment with chemotherapy and radiotherapy.

During the fourth course of chemotherapy, the patient's state aggravated quickly, with signs and symptoms of acute cardiorespiratory failure.

The symptoms described earlier were resolved under treatment with Cefort Tienam, Dopamine, Tramadol, Furantril, ACC, HHC, tapping, physiotherapy, secretion aspiration, Brofimen, the patient being transferred to Oncology.

Later evolution of the disease was aggravated by the appearance of some complications: acute enter colitis reflecting the immunosuppressed state, hepatocytolisis syndrome, iatrogenic Cushing syndrome, thrombocytopenia secondary to CHT (chemotherapy).

Under an objective clinical examination, it was observed that the general state of the patient was extremely poor, with preserved consciousness. The child presented Cushingoid facies, ringed, with pale skin, dry, with multiple bruises and stretch marks post-venous, with peripheral cooling trend. The patient had aphthous stomatitis and dry lips, muscular system hypotonic and hypokinetic weakness. Stetacustic lung could detect the presence of a coarse vesicular murmur with disseminated bronchial rales on both lung areas.

Heart sounds were rhythmic, cardiac frequency of 84b/min and blood pressure of 97/40mm Hg. In the digestive system, slowed intestinal transit was present, lack of appetite, hepatomegaly 3-4 cm below the costal margin, of soft consistency, with rounded front edge.

Patient reacts only to painful stimuli, balance disorders and psychomotor retardation specific to age.

Laboratory examinations could reveal the presence of microcytic hypochromic anemia, thrombocytopenia and absent inflammatory markers, hepatic cytolysis syndrome, hyperglycemia, remaining examinations were within normal limits.

Electrocardiogram showed sinus tachycardia 140b/min, QRS axis +30 degrees, PQ = 0.12 and rounded T waves in all leads (fig. 1, 2).

Chest radiograph (postero-anterior incidence) showed lung drawing accentuated hiliobazal, bilateral and heart displayed on the diaphragm (fig. 3).

Given the patient's neurological status,

computed tomography performed on 15.12.2008 was reconsidered, an examination which confirmed the diagnosis of glioma Pontin (fig. 4, 5, 6, 7),

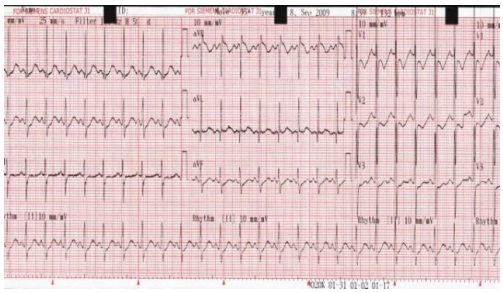

Fig.1. EKG – sinus tachycardia

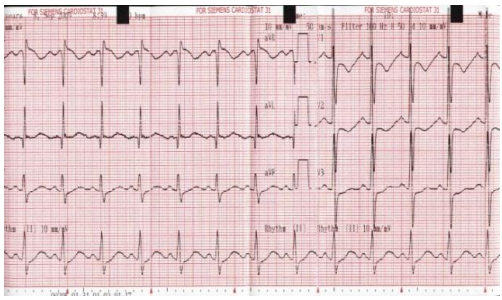

Fig. 2. EKG – where T rounded in all leads

Fig. 3. Chest radiography – accentuated lung drawing hiliobazal, bilateral, heart displayed on the diaphragm

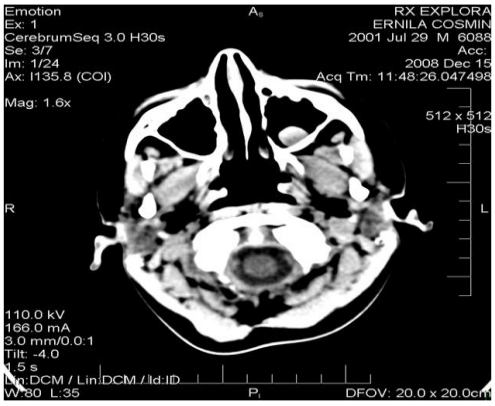

Fig. 4. Cranio-cerebral computer tomography - glioma Pontin

Fig. 5. Aspects of computed tomography

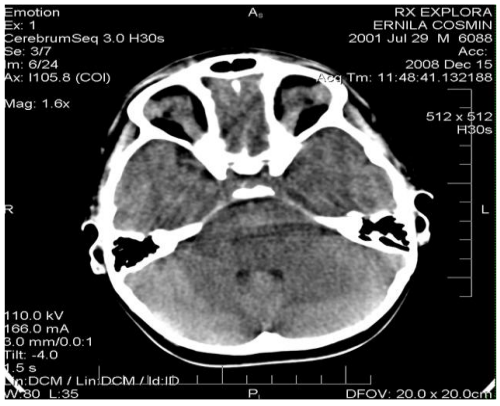

Fig. 6. Aspects of computer tomography

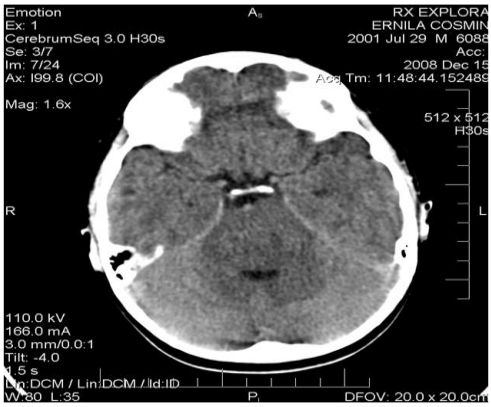

Fig. 7. Aspects of computer tomography

Neurosurgical examination revealed that the patient was conscious, with poor cooperation and left hemiparesis.

Doppler echocardiography performed on 08/06/2009 showed an intraventricular vegetation 1/1cm, located at the apical level that does not cause hemodynamic disturbances (fig. 8). Route ECG performed immediately revealed paroxysmal supraventricular tachycardia, AV = 170b/min, PQ = 0.12 and indefinite electrical axis with biventricular overload. Cardiothoracic radiography reveals a pronounced lung and heart drawing displayed on the diaphragm.

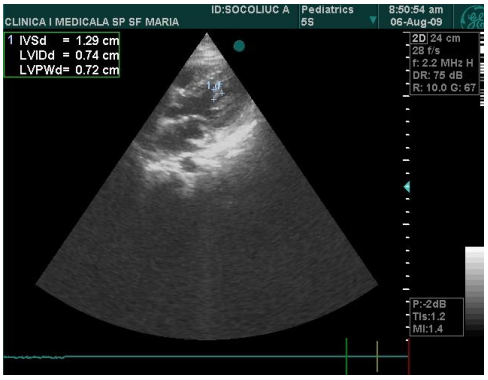

Fig. 8. Aspects of echocardiography Vegetation on apical level of the left ventricular

Echocardiography performed on 11.09.2009 highlights hiperechogene formation with dimensions of 1.52 mm / 0.57 mm VMA at the top left ventricular formation of 1/0, 4cm, VMA perforation, mitral insufficiency degree III, severe tricuspid degree III, pulmonary insufficiency degree III, raising the suspicion of pulmonary valve endocarditis (fig. 9).

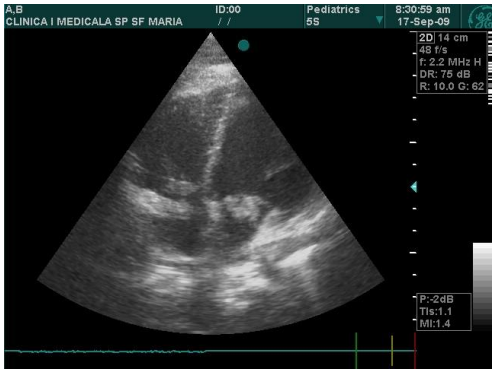

Fig. 9. Aspects on echocardiography Vegetations on mitral valve and tricuspid valve

The echocardiography performed on 17.09.2009 the endocarditis is diagnosed with 5 locations: mitral valve, aortic valve, pulmonary valve, tricuspid valve and ventricular tip.

During admissions, the patient was given antibiotics in dual therapy, initially with Ciprofloxacin Targocid and subsequently with Tienam and Cefort, for hemodynamic support Dopamine was administered, and Spironolacton for cardiac function, Furantril, under which the evolution of symptoms was weakly positive, finally, the patient died.

Final diagnoses were: 1. brainstem glioma; 2. syndrome pontomezen-cephalic; 3. VI nerve paresis left; 4. convergent strabismus left eye; 5. postchemotherapy ane-

mia; 6. secondary thrombocytopenia, aphthous stomatitis; 7. endocarditis with five locations: mitral valve, aortic valve, pulmonary valve, tricuspid valve, top right ventricular; 8. perforation of anterior mitral valve, 9. sinus tachycardia; 10. hepatic cytolysis postchemotherapy.

CONCLUSIONS

The peculiarity of the case lies in the presence of five outbreaks of endocarditis. The first ultrasound localization was described on 06.08.2009 at the top of right ventriclem, size of 1/1 cm after the patient received broad spectrum antibiotics and antifungal agents, and one month later it was described in other four sites of endocarditis.

This is explained by the patient's immunosuppressed status (by chemotherapy with Temodal). Also, chemotherapy is responsible for anemia, thrombocytopenia, hepatic cytolysis syndrome and nitrogen retention syndrome.

During the 9 hospitalizations, the patient had an episode of paroxysmal supraventricular tachycardia, for which he received treatment with metoprolol, this was the only episode.

Another feature of the case is the age of cerebral glioma–being outside the two peaks of incidence of the disease by age.

Patient prognosis was reserved, finally the patient died despite of all the efforts.

The prognosis of infectious endocarditis was also reserved as the etiologic agent could not be identified; the mortality reported in literature is of 20-25%.

Glioma Pontin has the worst prognosis, with average survival of 9-12 months, despite treatment, the patient survived nine months after being diagnosed.

Favorable prognosis factors in glioma Pontin are represented by neurofibromatosis, symptoms of less than 12 months before the diagnosis, exofitic localization, favorable histology, extra cervico medullary or focal tectal tumors, and calcification on computed tomography. Factors of unfavorable prognosis are under 2 years, with cranial nerve palsy and unfavorable histology.

IMPORTED HUMAN RABIES CASES WORLDWIDE

Authors from the Institut Hospitalo-Universitaire Méditerranée Infection, Marseille, France, carried out a study about 60 cases of human rabies in international travelers, reviewed from 1990-2012. A significant proportion of the cases were observed in migrants or their descendants when emigrating from their country of origin or after a trip to visit friends and relatives or for other reasons (43.3%). The cases were not necessarily associated with long-term travel or expatriation to endemic countries; moreover, cases were observed in travelers after short trips of two weeks or less. A predominance of male patients was observed (75.0%). The proportion of children was low (11.7%). Cases from India and Philippines were frequent (16 cases/60). In a significant proportion of cases (51.1%), diagnosis was challenging, with multiple missed diagnoses and transfers from ward to ward before the final diagnosis of rabies. Among the 28 patients whose confirmed diagnosis was obtained ante-mortem, the mean time between hospitalization and diagnosis was 7.7 days (median time: 6.0 days, range 2-30) including 4 cases with a diagnosis delayed by 15 or more days. In 5 cases, a patient traveled through one or more countries before ultimately being hospitalized. Factors that played a role in delaying the diagnosis of rabies in a number of cases were a low index of suspicion for rabies in countries where the disease has been eradicated for a long time or is now rare, a negative history of animal bites or exposure to rabies, and atypical clinical presentation of the disease. Clinical symptomatology of rabies was complex and commonly confuses physicians. Furthermore, failure in diagnosing imported cases in more developed countries is most likely related to the lack of medical familiarity with even the typical clinical features of the disease. MENINGITIS SEPSIS AFTER IUD INSERTION, A CASE PRESENTATION (Abstract): *Neisseria meningitidis* is a normal commensal of human mucous membranes that is no longer considered to be restricted to the nasopharynx. Due to the practice of oral sex, the mucous membranes of the cervix, urethra or anus have become a potential infection site for this bacterium. Inserting an intrauterine device (IUD), can alter the protective barrier of the endocervical mucosa, allowing for bacterial infection and systemic spread. We present a case report of a 40-year old woman who presented with abdominal pain, spotting and fever after inserting an IUD and developed a fulminant septical shock. Blood cultures and cultures from ascites showed the presence of *Neisseria meningitidis* group Y. From our knowledge, there are a few cases presented in the literature of toxic shock syndrome after IUD insertion, caused by *Staphylococcus aureus* or *Streptococcus* group A, but this is the first case of meningococcal sepsis after IUD insertion described. So, even though IUDs rarely cause significant infection, physicians should consider this device as a possible source in reproductive-aged women with the clinical features of sepsis. **Keywords**: MENINGOCOCCUS, IUD, SEPSIS

Neisseria meningitidis, an encapsulated, gram-negative diplococcus, is a normal commensal of human mucous membranes. It is no longer considered to be restricted to the nasopharynx, although this is the most frequent site identified as its reservoir (1). Meningococci are spread through respiratory droplets, normally requiring close and prolonged exposure or direct contact with saliva and respiratory secretions. Spread can occur from an asymptomatic carrier or from a patient who is ill. Occasionally, shortly after the onset of colonization, *N. meningitidis* strains might penetrate the mucosal membrane and gain access to the bloodstream. Bacteria that are able to survive and multiply in the circulation may then cross the meninges and gain access to the cerebrospinal fluid. Of the various forms of meningococcal disease, the most common ones are meningitis and severe sepsis with often a rapid fatal outcome (2).

Due to the practice of oral sex, the mucous membranes of the cervix, urethra or anus have become a potential infection site for this bacterium, and by inserting an IUD, the protective barrier of the endocervical mucosa can be altered, allowing for bacte-

rial infection and systemic spread.

Genital infection caused by *Neisseria meningitidis* (*N. meningitidis*) is not a common infection met in a gynecological practice, even if over the years there have been described cases when *N. meningitidis* was isolated from the urogenital tract, mostly as associated with subclinical infection (3-5) but also with cervicitis and even with salpingitis and peritonitis (1, 6). From our knowledge no case of sepsis related to a gynecological meningitis infection after IUD insertion was described until now.

Intrauterine devices (IUD) are a common used contraceptive method and even if it is known their association with a slightly increased risk for pelvic inflammatory diseases(cervicitis,endometritis, salpingitis, peritonitis), it is considered that the benefits of IUD insertion generally outweigh the risks (7).

In this case report we present a young woman that suffered a fulminant meningococcal sepsis presumably after an IUD insertion.

CASE REPORT

A 40-year-old woman, in a stable relation for one and a half years, zero-gravid, presented in November 2012 to the Obstetrics and Gynecological hospital, Malmö, Sweden, with lower abdominal pain and spotting after inserting an IUD. Anamnestic, she was suffering from Sjögren's syndrome and in 1997 had been operated for thyroid cancer, now on substitution medication.

For two weeks back, inserted a Copper-IUD and have had since then low-moderate abdominal pain and vaginal spotting. She presents to the gynecological emergency department with abdominal pain and fever. Her triage vital signs were blood pressure (BP) 112/63 mm Hg, pulse 97 beats/min, and temperature 39.3°C.

Initial examination showed tenderness of the lower abdomen without muscular defense. There was a brownish discharge from the cervix at speculum examination and the patient reported severe pain on dislocation of the cervix and uterus. No adnexal masses were palpated. A wet smear of the vaginal discharge showed leukocytosis and clue-cells. Cervical specimens were taken for culture of pathogenic *Neisseria gonorrhea* and *Chlamydia trachomatis*. Vaginal ultrasound showed a normal uterus with the IUD lying in the endometrial cavity and normal ovaries; no fluid in the Douglas pouch was noted at that time. Venous blood proves showed a normal level reactive protein C at 1.7 mg/ml, WBC count 3.6/mm^3 and normal renal, hepatic and electrolytes values.

The diagnosis of endometritis is set and the patient is sent home with oral treatment with Doxycillin, Metronidazol and antiinflammatory. Seven hours later, she wakes up with abdominal pain, diarrhea, vomiting and rash and comes by ambulance to the emergency hospital with the initial suspicion of an allergic reaction to medication. The examination shows intense abdominal pain, an increased liver, peripheral cyanosis, hypotonia, petechiae, but no neck stiffness and normal lungs auscultation. Afebrile at incoming, in the next hour the temperature rises to 40°C, triage vital signs are now BP 90/60 mmHg, pulse 120beats/min. Laboratory results show WBC count 0.8/mm^3, platelets 11/mm^3, creatinine 165mg/dl, reactive protein C 67mg/dl, base excess - 10mmol/l and lactic acid 8mmol/l. Deteriorates fast, needing intubation. Cultures are taken from blood, urine, throat,

nose and an initial dose of Meropenem and Tobramicyn is administered. A CT thorax and abdomen without contrast, shows a lot of fluid in the abdomen, an increased liver with edema around the intrahepatic veins and bilateral infiltrates at the basis of the lungs with pleural fluid. With a fulminant progress of sepsis, the patient becomes anuric, with distended abdomen and marmorated extremities and coagulopathy. The IUD is removed and diagnostic laparoscopy is performed next morning but only via the camera port because of the patient's increased abdominal pressure. The image (of poor quality) shows normal appearance of the bowels that flow in serous fluid. The genital organs are not seen, but there are no signs of peritonitis or abscess. Culture from the ascites is taken.

In a matter of hours she develops dry gangrene in fingers and toes, probably after septic embolism and aggressive vasopressor treatment.

At this time the culture results become available and they are positive for *Neisseria meningitidis* group Y, in blood and the peritoneal fluid.

Under broad spectrum antibiotic treatment, respiratory support and continuous renal replacement therapy, the patient starts to recover, but ten days after admission, her evolution becomes unstable again with intense abdominal pain and hypotension, and requires laparotomy because of suspicion of internal bleeding. Under operation spleen rupture is found, presumably after spleen infarct as secondary complication to sepsis and a splenectomy is performed, the internal genitalia are also inspected but except some secondary fibrin deposits on the uterus, no other pathology is seen.

After another complication in form of candida sepsis with retinitis, she finally slowly recovers and after nine weeks of hospitalization, is discharged with planned follow ups at orthopedic, hand surgery, endocrinology and ophthalmology clinics.

DISCUSSION

Sepsis after insertion of an IUD is a rare condition. The few cases found described in literature referred to toxic shock syndrome after IUD insertion caused by Streptococcus group A (8, 9) and *Staphylococcus aureus* (10). We haven't found any case reporting meningococcal sepsis after an IUD insertion. In this case presentation, there was no available culture from cervix or from the removed IUD, but beside the positive blood culture, the only other positive culture for *N. meninigococcus* was in the peritoneal fluid. Since the patients symptoms started together with the IUD insertion, and her only complain was gynecological, this was considered the primary focus.

There are at least 13 serogroups of *N. meningitidis*, with the most important being serogroups A, B, C, Y and W-135 (11). Meningococcemia is defined as dissemination of meningococci into the bloodstream. The fundamental pathologic change in meningococcemia is widespread vascular injury characterized by endothelial necrosis, intraluminal thrombosis, and perivascular hemorrhage. Endotoxin, cytokines, and free radicals damage the vascular endothelium, producing platelet deposition and vasculitis. The deleterious effects of cytokines play a major role in the pathogenesis of meningococcemia by causing severe hypotension, reduced cardiac output, and increased endothelial permeability (12). Management should focus on the treatment of the urgent clinical issues in addition to the administration of specific antibiotic

therapy. Empirical antibiotic therapy for suspected meningococcal disease consists of a third-generation cephalosporin to cover the various other (potentially penicillin-resistant) bacteria that may produce an indistinguishable clinical syndrome (13).

As isolation of *Neisseria gonorrhea* has been reported from pharynx (14), findings of *N. meninigitidis* in urogenital sites has been also described over the years, most probably due to changes in sexual behavior and habits during the last few decades, where the majority of cases of infection occur via the urogenital contact, with the nasopharynx acting as the major reservoir in healthy carriers (3).

There have been found healthy carriers of meningococci in urethra, cervix and rectum in both males and females, where meningococci were isolated from pharynx of partners (15,16). There are also cases described of urethritis, anitis cervicitis, salpingitis (1, 3, 6, 16) associated with the presence of *N. meninigitidis.*

CONCLUSIONS

Even though IUDs rarely cause significant infection, emergency physicians should consider this device as a possible source in reproductive-aged women with the clinical features of sepsis. And since the isolation of *Neisseria meningitidis* has been reported from urogenital sites, it is recommended in cases of suspected sepsis related to an IUD insertion to take also in consideration *Neisseria meningitidis* as a potential pathogen, along *Streptococcus group A* and *Staphylococcus aureus.*

NEWS

MESOTHELIOMA NOT ASSOCIATED WITH ASBESTOS EXPOSURE

Despite asbestos being identified as the single most important cause of malignant mesothelioma, the tumor is known to occur in only 10% to 20% of heavily exposed individuals. In addition, about 20% of the patients have no history of asbestos exposure even after detailed assessment. It should be realized that although there is a strong link between the development of malignant mesothelioma (MM) and asbestos exposure, not all cases are etiologically related to asbestos exposure. The proportion of cases attributable to asbestos exposure varies between the sexes and country, according to occupation and use of amphibole asbestos. A number of other agents have been implicated in the causation of MM but the best evidence appears to relate to another mineral fiber erionite and to irradiation. Erionite has emerged as the most important example of non asbestos-mediated cause of mesothelioma in regions such as Turkey where exposure to this type of fiber is highly prevalent. Ionizing radiation is a recognized human carcinogen and an established risk factor for several different types of cancers including hematologic malignancies and solid tumors. Cases of MM of the pleura, peritoneum, and pericardium have been reported in humans after therapeutic irradiation and thorium dioxide administration. Also, there is a strong experimental, epidemiologic and molecular evidence to suggest a possible carcinogenic or cocarcinogenic role of viruses such as SV40, a monkey polyoma virus, in the induction of MM. Although the polyoma virus SV40 has been unexpectedly discovered as an effective cocarcinogen of asbestos in the causation of animal mesothelioma, its potential role in human mesothelioma remains unproven. (Bharat Jasani, Allen Gibbs. Mesothelioma Not Associated With Asbestos Exposure. Arch Pathol Lab Med. 2012;136:262–267).

A CASE OF TURNER SYNDROME ASSOCIATED WITH SEVERE COARCTATION OF THE AORTA

Alina-Costina Luca[1], C. Iordache[1], Elena Braha[2]

University of Medicine and Pharmacy "Grigore T. Popa"-Iasi
Faculty of Medicine
1. Discipine of Pediatrics
2. Discipline of Medical Genetics

A CASE OF TURNER SYNDROME ASSOCIATED WITH SEVERE COARCTATION OF THE AORTA (Abstract): Turner Syndrome (TS) is a chromosomal abnormality due to the complete or partial lack of chromosome X, with clinical polymorphic elements: small size, hypogonadism, various visceral abnormalities. About half of the cases may suffer from congenital heart abnormalities. We describe hereunder a case of TS diagnosed with coarctation of the aorta due to high blood pressure detected by accident. **Key words:** TURNER SYNDROME, COARCTATION OF THE AORTA

Turner Syndrome (TS) is a chromosomal abnormality due to the complete or partial lack of chromosome X. TS incidence is about 1 case/ 2500 new-born female babies. TS pregnancy frequency is much higher, and many foetuses are lost by miscarriages (10% of miscarriages have TS). The TS syndrome is a generic one, the most common chromosomal abnormality being homogeneous monosomy 45,X (55% of the cases), followed by structural abnormalities of chromosome X (25% of the cases) and one normal cell line mosaic in 20% of the cases.

The clinical symptoms vary, whereas the subjects' psychological and motor development is within normal limits. At birth, this condition characterized by the subjects' small size, upper and lower limb lymphedema, webbed neck; 5% of the cases have severe cardiac malformations (severe coarctation of the aorta) requiring urgent surgery. The characteristics that are constantly present during childhood, adolescence and adulthood are the subjects' small size and, with age, delayed puberty, ovarian failure and infertility (1, 2).

These are accompanied with less common conditions such as: autoimmune diseases (thyroiditis, diabetes mellitus, celiac disease). 44.5% of the cases have congenital heart abnormalities (less severe coarctation of the aorta, bicuspid aortic valve, pulmonary and coronary artery abnormalities), whereas 40% of the patients suffer from early hypertension since their adolescence (3). The diameter of the aorta must be monitored the subjects' whole life, as there is a risk of aortic dilatation. Hypoacusis due to frequent otitis and horseshoe kidney are also included in this category (4, 1).

Medical management consists of growth hormone therapy during childhood, then

estrogen-progesterone supplementing during puberty. Trans-thoracic echography is recommended even when no clinical symptoms are present and is designed to detect possible aortic valve abnormalities or aortic dilatation (5).

The subjects' life quality, self-esteem and social integration are much better when puberty is not induced too late. The prognosis depends on the associated abnormalities: congenital heart abnormalities, hypertension, diabetes mellitus, obesity, thyroiditis, osteoporosis (2).

CASE REPORT

Patient DRM, aged 14 years and 3 months, came for primary amenorrhea, repeated hypertension (highest value 150/80 mmHg) and systolic murmur.

Family medical history. The patient is the second child of an unrelated apparently healthy couple, the mother 31 years of age and the father 37 years of age (at the time of conception). No other congenital anomalies, genetic diseases or reproduction disorders run in the family.

Personal physiological history. The pregnancy had a normal evolution. The birth was a term birth, the delivery was natural, head first, APGAR score 7 (1), weight 2000g, upper limb lymphedema. No data on the size and head circumference at birth were available.

Personal pathological history. The patient's first medical examination occurred when she was 13 years and 11 months old, in the endocrinology ward, where she went for primary amenorrhea. High blood pressure and systolic murmur are detected on this occasion, for which reason she was referred to the pediatric cardiology clinic.

Status upon hospitalization (14 years 3 months). The clinical examination reveals: small size (G = +1.16 DS, T = -2.33 DS, Pc = +0.88 DS), normally colored teguments and mucous membranes, lymphedema on the dorsal surface of the hands and feet, webbed neck, hard and soft palate dysmorphism, great inter-nipple distance, low hair level on the nape, many nevi. Slightly dysmorphic facies, earns positioned low and slightly flaring nose. Athletic constitution with broad shoulders and narrow hips. The patient also had cubitus valgus, clubfoot, shortening of the 4-5 metacarpal and metatarsal bones, hypoplasic nails and kyphotic-scoliotic posture. As concerns the cardiac system, we noticed the presence of collateral circulation in the thoracic cage, a III/6 degree systolic murmur in the left II-III intercostal space with interscapular-vertebral irradiation and in the epigastric region, clear peripheral pulse in the radial arteries, weaker pulse in the lower limbs (dorsalis pedis artery and posterior tibial artery, which is possibly also due to the lymphedema). The blood pressure was 160/80mm Hg in the upper limbs, and 140/70mm Hg in the lower limbs. The patient also complained of vertigo, fronto-occipital cephalalgia and bilateral hypoacusis.

During her hospitalization we detected high blood pressure (150/80 mmHg); the results of the complete blood count, hepatic and renal tests, glycemia and urine tests were normal; the fist X-ray reveals that the bone age is in agreement with the chronological age, fertile growth cartilages; the pelvic echography reveals that both kidneys have normal morphology, uterus 25/9.9/26 mm, left gonad 15.5 mm, no right gonad is detected; the hormonal tests reveals subclinical hypothyroidism (TSH = 7.47 µUI/ml, fT4 = 17.95 pmol/l, AAT-PO = 8.82 UI/ml); thyroid echography – hypoechogeneous thyroid.

Echocardiography revealed a severe aortic coarctation.

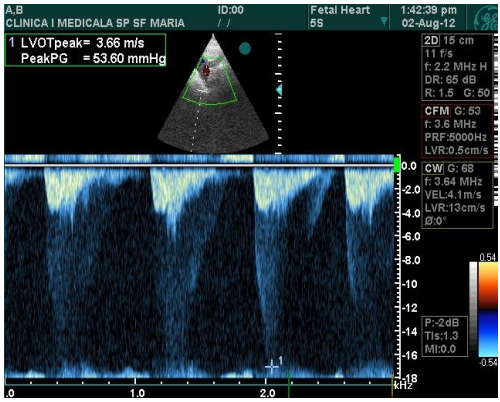

Fig. 1. Patient D.R.M.: echocardiography (suprasternal view) - severe coarctation of the descending aorta

The genetic examination sets a certain diagnosis, namely Turner Syndrome, homogeneous monosomy X, karyotype 45,X.

As a coarctation of the aorta was suspected based on clinical grounds, a thoracic angio CT scan was performed, which revealed a significantly narrowed area (0.73 cm diameter) on the descending thoracic aorta 0.8 cm below the origin of the left subclavicular artery; the caliber of the ascending aorta was 3.27 cm (2.14 cm in the prestenotic area and 2.06 cm in the poststenotic area); considerable collateral circulation visible in the cervico-dorsal area, dilatation of the left subclavicular artery 1.42 cm, of the right brachiocephalic arterial trunk 2.16 cm, of the internal thoracic arteries and of the collateral branches of the descending thoracic aorta; partially aberrant pulmonary venous drainage with possible aterio-venous fistula, pulmonary perfusion disorders. The spine was also affected (spine compression at the level of the D3 and D12 vertebrae, D5-L1 multiple intrabody disk herniations and slight kyphosis.

The final diagnosis was Turner Syndrome by homogeneous monosomy X, tight coarctation of the descending thoracic aorta, subclinical hypothyroidism, lower limb lymphedema, kyphosis.

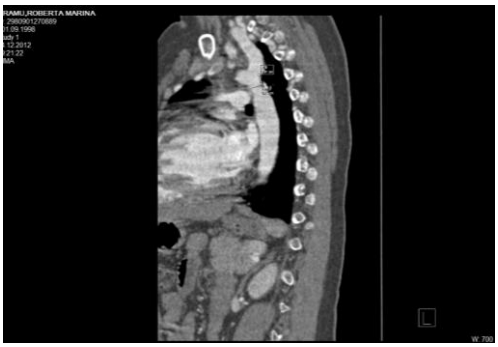

Fig. 2. Patient D.R.M – Angio-CT: area narrowing descending thoracic aorta, the vertebral body subsidence cuneiform D3, D12, D5-L1 multiple intrabody disk herniations and slight kyphosis

Fig. 3. Patient D.R.M – descending aorta coarctation

Therapy

We recommended endocarditis prophylaxis, specific hypertension therapy and avoidance of physical exertion. Measures should be taken to prevent the complications of congenital abnormalities, either by dilating the stenosis area by means of a balloon and stent, or by specific surgical procedures (6). The proband will also be given Euthyrox 100 μg/day for her subclinical hypothyroidism.

Evolution and Prognosis

The asymptomatic forms of coarctation of aorta are detected due to high blood pressure values accompanied by cephalalgia, repeated nosebleed or after a stroke. The prognosis depends on the success of the cardiac abnormality treatment and on hypertension persistence after surgery.

Given the patient's bone age, ~ 14 years, and her heart abnormality, GH therapy is tardy and will be avoided. The management of female patients suffering from Turner Syndrome proposed by Kavoussi et all. includes cardiologic supervision in outpatient clinics even when there are no clinical signs, blood pressure measuring on each visit to the doctor, renal echography and aggressive urinary infection therapy, TSH, glycemia and cholesterol dosing, annual hepatic tests, early scoliosis detection, hypoacusis due to repeated otitis, growth hormone therapy until the bone age of 15 years, then estrogen-progesterone therapy, integration in a support group and psychological counselling designed to prevent any psychosocial integration difficulties (7, 8).

As literature reports a frequent association between TS and autoimmune diseases (Hashimoto thyroiditis, type 1 DM, celiac disease, juvenile rheumatoid arthritis, psoriasis, veal skin) and since the patient already has subclinical hypothyroidism, careful pediatric follow-up is required for the early detection of such complications (9).

The specificity of the case consists of the association between a coarctation of the descending thoracic aorta, a severe form diagnosed at the age of 14 years, and the Turner Syndrome.

CONCLUSIONS

The clinical manifestations, extremely suggestive of Turner Syndrome and of cardiac abnormality, require early genetic and cardiologic exploration for a certain diagnosis setting, adequate therapy and prevention of serious possible complications of the coarctation of the aorta.

IS THERE A RISK FOR LYMPHOMA OR EXTRACOLONIC CANCER IN PATIENTS WITH INFLAMMATORY BOWEL DISEASE?

Elena Toader, Irina Ciortescu
University of Medicine and Pharmacy „Grigore T. Popa" – Iasi,
Faculty of Medicine
Institute of Gastroenterology and Hepatology - Iasi

IS THERE A RISK FOR LYMPHOMA OR EXTRACOLONIC CANCER IN PATIENTS WITH INFLAMMATORY BOWEL DISEASE? (Abstract). An important issue in the management of inflammatory bowel disease (IBD) is the risk for lymphatic or extracolonic malignancies reported in patients receiving prolonged immunosuppressive therapy and/or therapies with biological agents. Azathioprine (AZA), 6-mercaptopurine (6-MP), methotrexate, and anti-TNF (infliximab, adalimumab) are reference drugs for IBD forms unresponsive to conventional therapies. The administration of these drugs is a high responsibility because IBD itself is associated with an increased risk for cancer, namely colon cancer. The possibility of a drug-induced additional risk remains controversial, the relative risk for lymphoma being estimated at 1.2%. For extracolonic malignancies, there are variations in standardized incidence per reference population in terms of location (skin, liver and biliary tract, uterine cervix, prostate, etc.), and also IBD phenotype (ulcerative colitis or Crohn's disease). The uncertainty regarding the occurrence of neoplasia in IBD patients for many years on immunosuppressive therapy and/or biological agents is a strong argument both for treatment discontinuation and it's monitoring by inclusion in screening programs. In this paper we aimed to approach the conceptual model risk-benefit in the therapy with imunosuppressive and biological agents given the controversies in the literature generated by the drug-induced risk for malignant lymphatic and extracolonic tumor in patients with IBD. **Key-words:** INFLAMMATORY BOWEL DISEASE, EXTRACOLONIC CANCER, LYMPHOMA.

Inflammatory bowel disease (IBD) is a condition of chronic intestinal inflammation of unknown cause that includes two entities with distinct clinical and morphological features: ulcerative colitis (UC) and Crohn's disease (CD). In UC inflammation is limited to mucosa and is present only in the rectum and colon, and in CD the inflammatory process is transparietal and may affect any segment of the digestive tract, from mouth to near the anus (perianal disease). Descriptive epidemiology data show that IBD is a common disease worldwide, with large region-to-region variations in incidence. In the United States about 2 million people are affected and the worldwide incidence of UC is 0.5 to $24.5/10^5$ inhabitants (1). Europe is characterized by an uneven distribution of the disease, while South-Eastern Europe is less exposed to the risk of disease occurrence, fact supported by the low incidence in this area. In Romania the incidence of IBD is low, with an epidemiological profile dominated by the frequency UC, the incidence of which is approximated to $1/10^5$ inhabit-

ants. Regional data from a 2006 study in North-Eastern Romania show an IBD incidence of $1.75/10^5$ inhabitants, with an upward trend for CD and severe forms, mainly of UC (2).

IBD AND COLORECTAL CANCER

An IBD feature is the occurrence during disease progression of colorectal cancer (CRC), first recognized as a complication of UC in 1925 by Crohn and Rosenberg (3). Since then, several epidemiological studies have confirmed this increased risk, but its magnitude remains controversial due to variations in diagnostic methods. CRC occurs in 2-4% of patients with UC and accounts for 1% of all colorectal cancers in the general population (4). A number of factors that define the clinical features and progression of this disease, alone or in combination, may increase or decrease the risk for CRC. Factors associated with this increased risk are: disease duration, extension of colitis, sclerosing cholangitis (SC), family history of CRC, early onset of disease, and severity of inflammation (5). Main factors correlated with the risk for CRC are disease duration and extension. Early and prolonged exposure of intestinal mucosa to chronic inflammation is responsible for the occurrence of metaplasia - dysplasia - neoplasia sequence (6).

This context requires the use in this population group of endoscopic surveillance methods (colonoscopy) for cancer detection. A prerequisite in lowering this risk is mucosal healing with restoration of normal structure and function. This goal requires the administration of drug groups with immune mediation actions which are responsible for inducing long-term immunosuppression, thus increasing the risk for the occurrence of lymphoma and extracolonic cancer. The risk of extracolonic cancer in IBD patients is increased both by chronic intestinal inflammation and immunosuppressive treatment. This is a concern both for doctors and patients when treatment with purines and/or anti-TNF agents is considered.

One example is azathioprine (AZA), which by being incriminated in the increased risk for malignancy in patients with rheumatoid arthritis or kidney transplant, drew attention to the likelihood of increased risk in IBD patients on long-term immunomodulatory therapy. However, the risk of long-term immunomodulatory therapy-induced cancer remains controversial in both theory and practice, because IBD itself is associated with an increased risk for cancer, and most published studies found no risk for lymphoma or cancer with 5-year treatment; this needs to be also demonstrated for much longer treatments (7). It clearly comes out that the responsibility of gastroenterologists who use these drugs is high, and that he has to be aware of both its benefits and risks in order to provide optimal care to IBD patients.

We now present the drug classes used in IBD and the results of studies on the risk of extracolonic cancer and lymphoma.

THERAPEUTIC PRINCIPLES IN IBD

IBD is a group of chronic diseases, continuous or recurring in flares interrupted by remission, which requires long term, sometimes lifetime, treatment. The therapeutic goals are focused on inducing remission and maintaining it, with the ultimate goal of mucosal healing, which decreases the risk of cancer. Induction treatment aims at controlling clinical signs, reducing acute complications rate, and improving the qual-

ity of life.

Remission induction therapy uses the following drugs classes over a limited period of time:

- 5-aminosalicylate acid derivatives (5-ASA, mesalazine), used only in mild and moderate UC; historically, sulfasalazine and mesalazine, were used for remission induction in mild and moderate forms of CD, but cumulative evidence from different studies indicate that these drugs are less or even ineffective in treating patients with CD (8);
- corticosteroids, represent the most effective therapeutic group in inducing clinical remission used in the treatment of flares in the moderate and severe forms of IBD, or in cases with insufficient response to aminosalicylate treatment; corticosteroids include agents with oral, parenteral and topical administration. The use of corticosteroids in the treatment of IBD is based on its multiple immunosuppressive and anti-inflammatory actions intervening as a modulator or suppressor (high dose) in the production of inflammatory and immune response mediators; their effectiveness is proven if used properly, but no more than three months to avoid corticodependence (inflammatory recurrence when drug discontinuation or dose reduction are attempted) or corticoresistance (persistence of clinical manifestations on treatment) reported in approximately 50% of patients who required hormone treatment (9);
- biological therapy, represented by anti TNF alpha antibodies, is useful both in moderate- severe UC and CD (10);
- cyclosporine, is the drug of choice in toxic megacolon from UC; side effects limit its long term use and dosage (11).

Long-term maintenance of remission is sometimes a life time treatment. If some therapeutic classes, such as 5-ASA derivatives, prevent the risk for CRC, other drug groups (immunomodulators and biological agents) are incriminated in the increased risk for lymphoma and extracolonic cancer.

The drug classes used for maintenance of remission are (12):

- 5-ASA (mesalazine), used only in UC;
- purines, represented by azathioprine, 6-mercaptopurine, and methotrexate, used in CD and in patients with UC who developed corticodependence;
- anti TNF alpha antibodies.

The groups of drugs with risk of extracolonic cancer are purines and biological agents. If data on long term purine therapy are numerous, for biological agents data are available since 1998, when Infliximab was approved for the treatment of moderate and severe CD. In 2007, Adalimumab (humanized monoclonal antibody) and in 2008 Certolizumab (Fab fragment of humanized anti-TNF) (13) were introduced in the treatment of these diseases. The latest class of biological agents is represented by Natalizumab, an anti-integrin α monoclonal antibody.

IBD AND HEMATOLOGIC CANCERS

Studies on large series of patients with IBD demonstrate an association between CD and non Hodgkin's lymphoma (NHL) and between UC and leukemia. CD-myelodisplasic syndrome relationship has not been proven, and in terms of increased risk of lymphoma in patients exposed to purines the available results are controversial. In IBD patients followed up for long periods of time (18 years, between 1983 and 2001) 9 cases of lymphoma were found, with the mention that no patient had received purines prior to the diagnosis (14).

Conversely, other studies show an increased risk of lymphoma in patients exposed to purines. AZA and 6-MP are involved in lymphoma occurrence in patients treated for rheumatoid arthritis and prevention of graft rejection. A therapeutically-induced additional risk remains controversial, the relative risk for lymphoma being estimated at 1.2% with an estimated incidence in the multiple IBD patient series of 0.2-0.4%.

In terms of quality of life, the benefits of a 4-year immunosuppressive therapy outweigh the risk of developing cancer, and with a 5-year treatment no risk of lymphoma or cancer was found. The uncertainty regarding the occurrence of neoplasia in UC patients for many years on immunosuppressive therapy is strong reason for treatment discontinuation (15).

With biological therapy, IBD patients undergo prolonged immunosuppression with increased risk for hematological cancer in cases previously treated with purines. But given that most patients treated with biological agents have a positive therapeutic history for purines (corticodependent and corticorezistant severe illness), it is not clear whether the event is specific to this class of drugs or may be considered as a side effect of purine treatment. Conclusions on the adverse effects of biological therapy are still a subject for debate. Experts have tried to answer these questions by multicenter, randomized, case control, case studies (ex. reference studies for the validation of biologic therapy in IBD - ACCENT I and ACCENT II). In a series of 1107 patients with CD who received infliximab, 9 cases of lymphoma (0.81%) were found, percentage similar to that in the control group (CD patients not receiving infliximab) (16).

In the Mayo Clinic study conducted on 500 patients with IBD treated with infliximab, of 7 detected cancers (non-lymphomas) two were lung cancers, possibly due to infliximab treatment (17). In a Danish series of 561 patients with CD treated with infliximab for the 4 cancers reported no such association was found, the conclusion being that the treatment with infliximab is cancer-risk free (18). Similar conclusions come from a series of 2319 CD patients treated with infliximab: 30 patients (1.29%) developed cancer, percentage comparable with the general population and placebo group (19). A meta-analysis of 21 placebo-controlled trials including 5356 patients treated with biological agents concluded that cancer risk is not increased by biological therapy (20). An Italian study on 404 patients with CD treated with infliximab *vs.* 404 CD patients without infliximab demonstrated the similar malignancy rate in the both groups (9 vs. 7). The conclusion is that anti-TNF alpha agents seem not to increase cancer risk.

As to the relationship NHL-anti-TNF therapy the results are controversial. Also controversial is the response to the question whether the association of biological agents with purines increases the risk of lymphoma. In reference studies on this topic there are both pro and con opinions. In Britain, in a series of 6,000 patients with CD and 10,000 with UC treated with biological agents the risk of lymphoma was 1.2, comparable to that of general population (21). In Sweden, the study of 47,000 patients with IBD treated with biological agents showed a slight increased risk for NHL in those within the first 5 years of CD (22).

A Canadian study on 21,000 patients with CD showed a significantly increased

risk of NHL in men, independent of the use of purine immunomodulators (23). In the Mayo Clinic study the two NHL cases of the 500 patients treated with biologic therapy also received AZA (8). The study of 3,493 patients with rheumatoid arthritis treated with biological agents without AZA identified 10 cases of NHL and no case in the control group (24). In the study on 8,905 patients with IBD treated with biological therapy, 11/13 patients with NHL were exposed to purines (25). Hepatosplenic T-cell lymphoma is a rare type of peripheral NHL, 200 cases being described in the literature most in patients on immunosuppressive therapy (post-transplant, HIV). For IBD, 8 cases of hepatosplenic T-cell lymphoma in young men (12-31 years) with CD, treated with infliximab and purines, have been reported. And with adalimumab treatment 9 NHL cases were reported in patients with CD treated with purines (26). Experts concluded that there is risk for NHL in young men (20-54 years) on biologic therapy and prior exposure to purines.

IBD AND EXTRACOLONIC CANCERS

Patients with IBD are at high risk for extracolonic cancer, especially those with CD. In a series of 6027 patients with IBD (2857 CD and 2672 UC) extracolonic cancer rate was 690/100,000, higher than in general population. In CD cancer rate is significantly higher than in general population, compared with UC where the risk is similar to that in general population (27). Extraintestinal cancers are localized in the liver and bile ducts, with the same risk from CD and UC, in case of associated of primary sclerosing cholangitis (28). Breast, prostate, and lung cancers in patients with IBD have the same risk as in the general population (29).

In recent years, an increased risk for cervical dysplasia associated with IBD was noticed, but it has been suggested that this risk is high in patients receiving immunomodulation therapy. However, there are few studies reporting data on the risk of cervical abnormalities in patients treated with immunosuppressants. Presumptions of therapeutic risk for cervical dysplasia in IBD are based on theories related to inadequate surveillance of human papillomavirus (HPV) infection in patients treated with immunomodulators and reactivation of latent virus in patients treated with anti-TNF. IBD patients treated with immunomodulators (AZA, MP, MTX) have an increased risk for abnormal Pap smears compared with healthy people. Regarding therapies with biological agents (anti-TNF), a recent study showed that infliximab does not increase the risk for abnormal Pap smears. Also, combination regimens of medicines prescribed for patients with IBD (oral or intravenous steroids, 5ASA and various combinations of infliximab, AZA and 6-MP) have no significant contribution to cervical abnormalities. Certain conditions, such as multiparity, prolonged use of oral contraceptives, number of sexual partners, smoking, and Chlamydia infection are considered additional risks associated with developing cervical cancer. The recommendation is that tests for Papilloma virus to be run before starting immunemodulatory and biological therapy, which, by way of action, can activate HPV (30).

CONCLUSIONS

Data in the literature on the theoretical potential for malignant extracolonic and lymphoma developments, practically con-

firmed in small number of IBD patients on treatment with immunomodulators and biological agents, are considered sufficient to promote strategies for selecting and monitoring these patients at risk for malignant complications with various locations.

NEWS

FIBROUS DYSPLASIA - A BENIGN BONE DISEASE WITH RARE POTENTIAL FOR MALIGNANT TRANSFORMATION

Fibrous dysplasia (FD) is an uncommon bone disease that has a rare but clear potential for malignant transformation. The diagnosis is usually not difficult given the symptoms, radiology, and histology. The histologic picture is classically of low to moderately cellular fibrous stroma surrounding irregularly shaped bone trabeculae without osteoblastic rimming, which matches the benign appearance on radiology. The gene involved in pathologenesis is a subunit of G-protein receptors, found on chromosome 20. Recent innovation in molecular pathology has helped us understand the mechanism of the disease, pertaining to cAMP and WNT/b-catenin. The treatment of FD is limited to maintenance of maximum bone density via diet, exercise, and therapeutic medications, with many patients also choosing to avoid substances that lower bone density, such as caffeine and nicotine. Oftentimes, surgical reinforcement is needed for bowing deformities and fractures when they occur. Currently, there is no therapy for preventing disease advancement or for malignant transformation. (Riddle ND, Bui MM. Fibrous dysplasia. *Arch Pathol Lab Med*. 2013;137:134–138).

CLINICAL – IMAGING ASPECTS OF YOUNG PERMANENT TEETH TRAUMAS AND THE ETHIOPATOGENIC MECHANISMS INVOLVED (Abstract): Dental trauma occurring to children and teenagers all over the world represents a serious issue in Public Health. **Aim:** This present study wants to investigate the etiology and the environment in which the dental trauma occurs and also wants to establish a connection between dental trauma and social-economic status. **Material and methods:** The study was made to collect information about dental trauma on human subjects involving 372 children and teenagers, both female and male, between 8 and 20 years of age. The data obtained from the clinical and radiological exams for each patient have been registered in a special conceived register, which represented a stage of the study. **Results:** The frequency of dental trauma varied from 62.1% for males to 37.9% for women. Most of them have suffered from dental trauma between the age of 14 and 16 (30.1%), and a few between 18 and 20 years (2.2%). Dental trauma has occurred most frequently in school, during sports lessons, followed by those in public places like the street (23.1%), from which 17.1 % have been associated with bicycle accidents, 3.5 % with scooter accidents and 2.5% with car accidents. Children and teenagers who live in areas with a low social economic level have been the fewest to seek medical attention due to difficult access to medical services. **Conclusions:** Overall, this study wanted to present the importance of knowing the frequency of dental trauma in children and teenagers and to point out the need of promoting medical education to parents regarding the means they can use to reduce the risk factors associated with dental trauma. **Keywords:** DENTAL TRAUMA ETIOLOGY, YOUNG PERMANENT TEETH, PREVENTION, CLINICAL AND IMAGING ASPECTS.

Dental trauma is acknowledged as a serious matter of Public Health amongst children and teenagers. These lesions can occur at young ages and are irreversible, painful; they involve high costs and complex treatments.

It has been proved that dental trauma has a psychological and social impact on children (1). Epidemiological studies have reported that one third of preschool children have suffered from trauma involving temporary dentition and a quarter of them have suffered from trauma involving the permanent dentition (2). According to the studies made by Andreasen et al. (3), dental trauma occurs frequently in childhood and adoles-

cence and statistics show that two thirds of the children have suffered from dental trauma before the adult period. Recent studies (1, 2, 4) on children between 11 and 13 years of age have reported a prevalence of 6.4% in South Africa, 11.2% in Malaysia, 12.8% in Nigeria, 13.1% in Turkey, 35% in Thailand, and 36% in Brazil. Dental trauma is continuously growing amongst children and teenagers due to their more frequent involvement in sports with contact, accidents, domestic fights and falls (4, 5). Few studies have evaluated the social economic indicators. An Australian study has presented an effect of the social economic status upon dental trauma as a result of sporting events (6, 7). On the other hand, Fakhruddin et al. (8) found a prevalence of dental lesions in the Canadian population of 11.5 % but with no statistic association between dental trauma and the parents' level of education, the family income.

The purpose of this study was to collect information about dental trauma of young permanent teeth amongst children and teenagers in Iasi. The specific objectives were to evaluate the epidemiological profile, the place of occurrence, the connection between the social economic status and these dental traumatic lesions.

MATERIAL AND METHODS

The study was made on human subjects involving 372 children and teenagers from both rural and urban environments in the district of Iasi, with ages between 8 and 20 that have come for treatment in the Prevention Clinic of the Faculty of Dental Medicine, University of Medicine and Pharmacy "Grigore T. Popa" - Iasi between 2008 and 2011. Each of these patients or their parents has signed an informed consent after the purpose and importance of this study had been explained to them.

The identification of the dental lesions was made by a team of assistant researchers and the main researcher in standard conditions. The diagnosis criteria used in this study has been set in detail before the beginning of the study. For each consult, the examiner wore gloves and used a sterile kit with a dental probe and a dental mirror. X-rays for the dental lesions were made for only 161 patients, using a digital roentgen device.

The data obtained after the clinical and radiological examination have been registered in a special chart for each patient in order to be able to evaluate statistically the parameters of interest.

RESULTS

All 372 patients that have been treated for dental lesions have agreed to participate in this study. The frequency of trauma of the young permanent teeth is twice higher in boys than girls, due to sports and games that are more violent for boys.

Most patients that have suffered from dental trauma have between 14 and 16 years of age and a few between 18 and 20 years. In this last interval, the dental traumatic lesions occur because of traffic accidents (tab. I).

In the etiology of trauma are involved numerous factors. Most important seem to be sports accidents, followed by traffic accidents, those due to aggressions , accidental falls and last but not least physical abuse (tab. II).

In tab. III it is shown that dental trauma is located most frequently at the frontal teeth because they are situated in such a way that they are exposed more at vulnerable agents. This explains the vestibular movement of the frontal teeth and the hypotonic of the upper lip.

TABLE I

The frequency of reported injuries to young permanent teeth by age group and sex

Age group (years)	Total		Male		Female	
	no	**%**	**no**	**%**	**no**	**%**
8 – 10	58	15.6	31	53.4	27	46.6
10 – 12	73	19.6	42	57.5	31	42.5
12 – 14	106	28.5	57	53.8	49	46.2
14 – 16	112	30.1	89	79.5	23	20.5
16 – 18	15	4.0	7	46.7	8	53.3
18 – 20	8	2.2	5	62.5	3	37.5

TABLE II

Frequency of various causes of dental trauma

Causes of dental trauma	no	%
Traffic accident	86	23.1
Sport at school	249	66.9
Falls and collisions	29	7.8
Physical abuse	8	2.2

TABLE III

Frequency of young permanent teeth that had a traumatic dental injury

Involved tooth	n	%
Maxillary		
Right lateral incisor (# 11)	43	12.8
Right central incisor (# 12)	98	29.1
Left central incisor(# 21)	137	40.7
Left lateral incisor (# 22)	59	17.5
Mandibulary		
Right lateral incisor (# 42)	12	13.6
Right central incisor (# 41)	31	35.2
Left central incisor (# 31)	36	40.9
Left lateral incisor (# 32)	9	10.2
Total	**425**	**100**

Out of all the patients, 78.2 % come from urban environment, 21.8 % from the rural one. The number of urban patients has been higher due to the superior level of living and easier access to medical service.

Traumatic lesions affect most frequently the central maxillary incisors. The patients with high over jet are more willing to have dental trauma. Raising the ove jet from 0-3 mm to 3-6 mm doubles the extend of the dental lesion, and a over jet of 6 mm triples the severity of the dental trauma. This is way the dental occlusion is a very important factor in producing traumatic

lesions. Most patients have had a traumatic occlusion (80.1 %) and only 19.9% of them have presented with normal occlusion.

The most frequent symptom was pain, reported by 48.8% of the patients. This was followed by physiognomic disorder (16.5%), dental mobility (11.4%) and coronary stains (16.0). Abrasion and contusion are present in a small percent (7.2%).

After the clinical and radiological exams performed on this human specimen, we have concluded that most patients had simple coronary fractures (43.3%), complicated coronary fractures (18.3%), coronary-root fractures (14.0%), fissures (10.4%) and root fractures only (9%). Dental dislocation has been present in 5% of the cases. In fig. 1, 2 we can observe two clinical cases that came and have received treatment in our clinic.

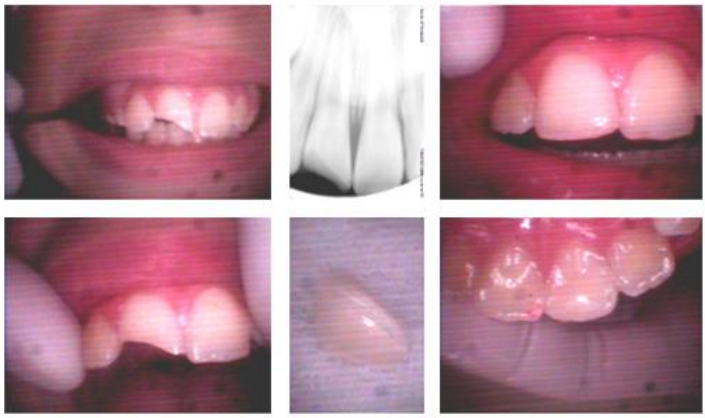

Fig. 1. Uncomplicated crown fracture.

Fig. 2. Extrusive dislocations.

DISCUSSION

The patients that have taken part in this study can be considered a representative population with ages between 8 and 20 years, but they do not represent the whole population of children and teenagers from Iasi district. The absence of signs and symptoms in the moment of the examination, in certain circumstances like dental dislocation and root fractures as well as the presence of the X-rays only for 161 patients, have reduced the estimation of dental trauma. This impediment has been shown in other similar studies made by other investigators.

These dental lesions affect 20-30 % of the population of the world regarding permanent dentition. They have psychological,

economical, functional and esthetic consequences. With such frequency of trauma, prevention has become the main target in Dental Traumatology.

Many epidemiological studies (9) regarding traumatic lesions have analyzed their etiology even though only a few have offered details regarding measures of precaution that should be taken. These studies made us understand better the clinical and biological aspects of the evolution and treatment of these pathological entities.

The statistic results are very similar to those studies made on the same subjects. The frequency of dental trauma in this study is twice as big for male subjects (62.1%) than female ones (37.9%). Furthermore, Glendor (10) have noticed a report of 2.5/1 in favor of the boys.

Most traumatic lesions have involved central maxillary incisors. This conclusion is the same in other studies as well and is explained by the anterior possition of these teeth on the dental arch (8, 9, 10).

A total of 66.9 % of the subjects participate regularly in a sports team, but none of them wear protection equipment during the sports activity. The reason for not using this equipment is the leak of information. This state's clearly the need of promoting public health in education institutions. The human subjects had been chosen because they are submitted to a high risk of developing dental trauma.

CONCLUSIONS

By promoting public health we must state the importance of the psycho-social impact on day to day life of children and teenagers that have suffered a dental trauma.

ANGIOTENSIN CONVERTING ENZYME INHIBITORS AND PULMONARY HYPERTENSION (Abstract): **Aim:** To evaluate the efficacy of angiotensin converting enzyme inhibitors Enalapril, Fosonopril and Moexipril on mean and systolic pulmonary artery pressure. **Material and methods:** The study included 111 patients with chronic obstructive bronchopneumopathies associated with arterial hypertension and mild to moderate heart failure (NYHA I-II class). The patients were examined at baseline and after 60 days of treatment. The central hemodynamic parameters and mean and systolic pulmonary artery pressure were studied by Doppler echocardiography (Phillips HD11XE). The pulmonary artery was viewed by left parasternal approach – cross section of the aorta. The following were measured: pulmonary artery flow acceleration and deceleration time (pafAT/ pafDT), right ventricular izovolumetric relaxation time (IVRT), mean and peak pulmonary blood flow velocities, right ventricular/pulmonary artery systolic pressure (RV/ PASP). The mean pulmonary artery pressure (MPAP) was estimated based on pulmonary flow acceleration time and right ventricular ejection time. **Results**: Following the treatment with angiotensin converting enzyme inhibitors a positive dynamics of SF pattern close to the normal one – a domelike contour with the maximum almost in the middle of diastole was noticed. **Conclusions**: the quantitative estimation revealed the considerable reduction in pulmonary artery systolic pressure (PASP) (from 46.3 ± 3.3 mmHg at baseline to 32.1 ± 2.6 mmHg after treatment, $p < 0.01$) and MPAP – from 26.7 ± 3.2 mmHg at baseline to 23.2 ± 2.6 mmHg after treatment, $p < 0.01$. **Keywords**: ANGIOTENSIN CONVERTING ENZYME INHIBITORS, CHRONIC OBSTRUCTIVE BRONCHOPNEUMOPATHY, PULMONARY HYPERTENSION, HEART FAILURE.

The cause of the disease has not been proven so far, but vasoconstriction represents an important pathogenic link of PH (1, 2, 3, 4).

Rennin-angiotensin-aldosterone system (RAAS) is important in maintaining vascular tone. The main role of RAAS dysfunction in systemic arterial hypertension (SAH) is well accepted, whereas in pulmonary hypertension it is less obvious.

MPAP > 60 mmHg revealed an increase in serum renin activity (SRA), aldosterone (AS), vasopressin (VP), converting enzyme activity, and AII concentration. Evaluating RAAS related to SRA, it was observed: RAAS increase in patients with PPH is an

adjunct to the increase in SRA, AII, AS and VP levels. Future research of the role of RAAS in the appearance and progress of PH could determine the strategy and a standardized treatment for PH in patients with obstructive lung disease (5, 6, 10, 11). The role of ACEIs in preventing pulmonary hypertension was demonstrated (e.g. use of Captopril and Cilazapril in hypoxic pulmonary hypertension led to hypertrophic changes in tunica media of pulmonary veins (12, 13, 14). The vasodilating effect of ACEIs might be less important than the humoral activity. Here, smaller doses of ACEIs may cause the blockade of RAAS and activate bradykinin to form L-arginine/ nitric oxide, and, it would not lead to systemic hypotension, thus being beneficial in patients with PH. Patients with PH presented a significant activation of RAAS which correlates with pulmonary artery pressure and severity of heart failure. The use of ACEIs in the treatment of patients with PH needs to be re-evaluated.

This study was aimed at assessing the efficacy of ACEIs Enalapril, Fosonopril and Moexipril on mean and systolic pulmonary artery pressure in patients with chronic obstructive bronchopneumopathy (COBP) in association with arterial hypertension (AHT) and mild to moderate heart failure (HF) NYHA I-II class.

MATERIAL AND METHODS

Group I: 61 patients (40 men and 21 women), aged between 18 and 65 years (mean age 46.1 ± 1.3 years) with moderate COBP (Tiffeneau index < 70%; 50% ≤ VEMS < 80%) associated with AHT and mild to moderate heart failure (NYHA I-II class). The patients were assessed at baseline and after 8 weeks of treatment with Enalapril (Ednyt, Geden Richter, Hungary), 10-40 mg once daily (mean dose 21.0 + 4.3 mg). *Group II*: 26 patients (12 men and 14 women, mean age 56 ± 0.9 years) with similar forms of COBP, treated with Fosinopril (Monopril, Bristol Myers Squibb, UK), 5-10 mg once daily (mean dose 7.3 ± 0.5 mg). *Group III*: 24 patients (8 men and 16 women, aged 54.4 ± 6 years) treated with Moexipril (Moex, *Schwarz Pharma*, Germany) 7.5 mg once daily – initially and after 60 days of treatment.

The central hemodynamic parameters and mean and systolic pulmonary artery pressure were studied by Doppler echocardiography (*Phillips* HD11XE), according to the traditional Teccholtz method (2, 3, 4). The pulmonary artery was viewed by left parasternal approach – cross section of the aorta. The sample volume was situated at the level of pulmonary artery distal the pulmonary valve or in the cone ejection of the right ventricle close to the pulmonary valve (thus highlighting the turbulent post valvular flow sample). The following were determined: pulmonary artery flow acceleration and deceleration time (pafAT/ pafDT), right ventricular izovolumetric relaxation time (IVRT), mean and peak pulmonary blood flow velocities, right ventricular/pulmonary artery systolic pressure (RV/PASP). To determine quantitative ratios we used Bernoulli's modified formula (3): $P = 4V^2$, where P – pressure gradient, V – flow velocity, m/ sec.

The pulmonary artery systolic pressure in PA (SPPA) was calculated upon the formula derived from L. Burstin's nomogram (7, 8, 9):

$$PAP = TIR + HR - 107.5$$

where TIR – RV izovolumetric relaxation time, m/ sec, HR-heart rate, beat/ min.

MPAP was estimated based on pulmonary flow acceleration time in the ejection

tract of the right ventricle (9): Log 10 (mPAP) = 2.8 AT/RVET + 2.4, where AT – pulmonary flow acceleration time (m/sec), RVET – right ventricle ejection time (m/sec).

RESULTS AND DISCUSSION

After the immediate test with Enalapril (5 mg) the hypertensive action of the preparation began within 1.5-2 hours, the maximum effect – over 4-6 hours, and duration of the action – 24-26 hours. After two months of Enalapril treatment, a significant decrease in SBP by 11.4% and DBP by 9.5% was noticed, $p<0.05$ (tab. I).

All patients had normal indices of left ventricular myocardial mass (< 120 g/ m^2), right ventricular telediastolic diameter (2.64 ± 2.015 cm), and right ventricular anterior wall thickness (5.77 ± 0.22 mm). The baseline qualitative estimation of SF at the pulmonary valve orifice and right ventricular outflow tract showed the predominance of typical forms of pulmonary hypertension (two waved, triangular or mixed). After treatment with Enalapril, the dynamics of the systolic flow pattern close to normal – domelike contour with the maximum almost in the middle of diastole was noticed. The quantitative assessment revealed the considerable reduction in PASP level (from 46.3 ± 3.3 mmHg at baseline to 32.1 ± 2.6 mmHg after treatment, $p<0.01$) and mPPA (from 26.7 ± 3.2 mmHg at baseline to 23.2 ± 2.6 mmHg after treatment, $p < 0.01$ (tab. II).

TABLE I

Dynamics of SBP, DBP and HR parameters after treatment with Enalapril

Ratios	SBP, mmHg	DBP, mmHg	HR, beat/ min
Baseline	172.5 ± 5.9	108.2 ± 3.9	75.1 ± 1.5
After treatment	137.5 ± 5.1**	87.2 ± 2.4**	71.5 ± 1.5

*p<0.05; ** p<0.001

TABLE II

Changes in pulmonary hemodynamic parameters after treatment with Enalapril

Ratios	PASP mmHg	TAPF, m/ sec	TIR, msec	TPR, dyn·cm·sec^{-5}
Baseline	46.3 ± 3.3	96.7 ± 2.5	78.6 ± 1.7	386.5 ± 22.7
After treatment	32.1 ± 2.6**	126.1 ± 3.0**	61.4 ± 2.9*	230.4 ±12.0*

In parallel, a significant reduction in total pulmonary resistance (TPR) and total vascular resistance (TVR): 386.5 ± 22.7 *vs.* 230.4 ± 12.0 dyn·sec·cm^{-5}, $p<0.05$ and 3200.4 ± 54.0 *vs.* 1850.5 ± 75.9 dyn·sec·cm^{-5}, $p<0.05$ were noticed. HR values were actually the same during the research (from 75.1 ± 1.5 beat/ min at baseline to 71.5 ± 1.5 beat/ min after treatment, $p>0.05$). Data analysis revealed a tendency towards the shortening of systolic acceleration time SAT) (< 100 msec) in the presence of pulmonary hypertension (SPPA > 32 mmHg) that can be used as a predictive criterion in the early stages of obstructive pulmonary disease. After treatment with Moexipril there was a statistically significant

reduction in SBP and DBP (by 12.9% and 10.2%, respectively) associated with a decrease in SPPA (42.1 ± 1.1 *vs.* 28.2 ± 0.8 mmHg, p<0.01), MPPA (from 28.0 ± 4.5 mmHg at baseline to 23.4 ± 2.1 mmHg after treatment, p<0.05), and TPR (424.5 ± 25.0 *vs.* 226.6 ± 15.5 dyn·sec·cm^{-5}, p<0.05) were also found (tab. III, IV).

TABLE III

Changes in pulmonary hemodynamic parameters after treatment with Moexipril

Ratios	PASP, mmHg	TASF, msec	FRI, msec	TVR, dyn·cm·sec^{-5}
Baseline	42.1 ± 1.1	104.4 ± 7.5	51.5 ± 2.2	2900 ± 33.2
After treatment	28.2 ± 0.8*	138.1 ± 10.0*	47.7 ± 1.7	1750 ± 57.4 *

TABLE IV

Dynamics of SBP, DBP and HR parameters after treatment with Moexipril

Ratios	SBP, mmHg	DBP, mmHg	HR, beat/ min
Baseline	160.9 ± 8.2	98.0 ± 3.4	98.2 ± 4.4
After treatment	140.1 ± 3.0*	88.1 ± 2.7*	86.1 ± 3.3 *

The patients treated with Fosonopril presented a significant reduction in TAS by 14.1%, TAD by 12.4% (p<0.01), and cardiac frequency by 10.1% (p<0.01). Also noticed was a significant decrease of SPPA from 35.3 + 3.07 mmHg to 23.1 + 2.64 (p < 0.01), APPA (from 28.0 ± 4.5 mmHg at baseline to 23.4 ± 2.1 mmHg after treatment, p<0.05), and TPR (424.5 ± 25.0 *vs.* 226.6 ± 15.5 dyn·sec·cm^{-5}, p<0.05). There was an inversely proportional correlation between TAPF and SPPA (tab. V).

TABLE V

Changes in pulmonary hemodynamic parameters after treatment with Fosinopril

Ratios	PASP mmHg	TAPF msec	TPR dyn·cm·sec^{-5}
Baseline	38.3 ± 3.1	112.4 ± 7.3	424.4 ± 16.6
After treatment	27.1 ± 2.6**	142.1 ± 6.5**	226.6 ± 15.5

* p < 0.05; ** p < 0.01

Thus, Fosinopril proved to be efficient in reducing SPPA and MPPA in patients with chronic obstructive bronchopneumopathies in association with AHT and moderate heart failure.

CONCLUSIONS

Angiotensin converting enzyme inhibitors reduce significantly after two months of treatment the systolic and mean pulmonary artery pressure and mean arterial pressure in patients with chronic obstructive broncho-

pneumopathies associated with AHT and mild to moderate heart failure. The qualitative and quantitative estimation of the systolic flow pattern at the orifice of pulmonary valve and across the right ventricular outflow tract allows the early diagnosis of pulmonary hypertension in patients with COBP. Right ventricular hypertrophy is a late and unnecessary sign of central and pulmonary hemodynamic disturbance in patients with chronic obstructive bronchopneumopathies and arterial hypertension; the key to establishing and creating the changes in the pulmonary hemodynamics is obviously the stable increase of systolic and mean pressure in the pulmonary artery.

MEDICAL AND ETHICAL DILEMMA IN BRAIN DEATH

Irina Streba[1], Simona Damian[1´2], Beatrice Ioan[2]

MEDICAL AND ETHICAL DILEMMA IN BRAIN DEATH (Abstract): For centuries, death has been defined, medically speaking, as the irreversible cessation of breathing and of nervous and cardiac activity. What radically changed this definition was the introduction of the concept "brain death" in 1968, by the"Ad Hoc Committee of the Harvard Medical School". According to it, the irreversible coma was associated with brain death and considered to be a criterion for the diagnosis of the deceased individual. The evergrowing need for transplant organs (provided this respects the dead honor rule, stipulating that organs can't be harvested unless someone is deceased) lead to making arbitrary decisions regarding the establishment of the exact time of death during the process of „losing life". What actually triggers the controversy related to the concept of brain death is the dilemma of associating this concept with that of biologic death or death of the person, the difference between the two being made by whether the mental characteristics are accepted or not in defining and individualizing the death of the human being. Given these circumstances, a dilemma appears- that of defining the death of the individual: we define death, as it has been for centuries, as the moment when the cardio-respiratory function no longer exists, which leads to the loss of tens of thousands of lives that might have been saved through transplant. Yet, this may lead to manipulating the border between life and death, with the risk of trespassing each individual's right to life.
Key words: BRAIN DEATH, ETHICS, IDENTITY.

Defining the death of a human being in a unitary and generally valid way is as relative and difficult as defining life itself, for the former depends directly on the latter, both relating to a sum of multiple, various ways of manifestation. Death is taken into account in terms of ways of seeing the world, or the individual, and it is reflected and conditioned by social organization, tradition, religion and so on.

Defining death also depends on the value system specific to each field of activity, the medical definition itself being influenced by philosophy, theology, scientific discovery and not to forget, political and social priorities, etc.

From a philosophical perspective, defining death depends on the one providing the definition. According to Hegel, the main figure of idealism during the 19th century philosophy, "death is the triumph of species over individual, thus underlining the benefits of the individual disappearance on the progress of the entire mankind" (1).

Epicurus stated that "...Death is nothing for us, for when we exist, it doesn't, and

when it comes up, we no longer exist. The whole of good or evil is given by sensations, and death is the very absence of such." This materialistic approach is based on the assumption that death is a spontaneous ending of our sensuous experience and, thus, a form of non-existence. Therefore the matter is not of transition, but simply an abrupt ending (2).

Camus, an important name for existentialism, asserts that every man is free to give meaning to his own death, an idea set on the borderline between idealism and materialism. Although hesitating to answer fundamental questions regarding the clash between life and anything that might come after, such a thesis emphasizes the very act of dying, a gesture that becomes fundamentally important in the man's interior and individual search (1, 3).

According to the Orthodox Church, death is, first of all, a spiritual phenomenon that stands for the primordial dismissal, the man's separation from Life, therefore God himself, as a result of disobedience. Physical death is the derived effect of spiritual death and it involves the separation of the soul from the body, the first step to going back to the Fountain of Life. This is why the patristic tradition calls the dissolution of the body "God's benefaction towards man, so that evil will not linger forever after" (4, 5).

Legally speaking, death is associated with the suspension of the individual's civil status, thus making him no longer be a subject to law.

Relating to physiological mechanisms, life represents the sum of the physical, chemical and mechanic actions through which the body accomplishes its functions: metabolism, reproduction, excitability. On this background, death may be seen as a process that brings these functions to an end, as a consequence of complete and definitive disappearance of input, transportation and use of oxygen at cell level (6).

Anthropologists define human life as a sum of three levels, interconnected and hierarchically placed: organic/ physiologic, psychic and social. The life of the organism is based on the integration and coordination of body functions necessary to maintain the organism as a whole. Psychic life depends on the physiologic one and, in the case of the adult, conscious man; it contributes to the perception, integration and reaction of the individual. Social life definitely requires for the previous two levels, and it represents the person's integration and status. Given this definition, one must sense the difference between the death of the biological organism and that of the person, the latter being the cessation of all three levels, the climax of which is the social life, places at the top of the hierarchy (7, 8).

THE CONCEPT OF BRAIN DEATH

If so far as the last few decades, death was the interruption of all three levels of life, the development of medical technology allowed that physiologic life to be maintained in situations where the psychic and social levels no longer exist. Still, there remains the question of life and death coexisting within the same body. If we are to speak only physiologically and to analyze death as a process generally known by means of the phrase "the cells are born together and die separately", then the answer is affirmative. Purely from a biological point of view, the individual's death is defined as disintegration of the body as a whole, but after its moment, certain organs and systems may still keep traces of life for different periods of time, depending on how long they can survive without oxygen

(for instance, the nervous cell dies within the first 3-5 minutes, whereas hair and nails may still keep a lively aspect for days) (9). Practically, however, medicine's technical possibility to maintain the cardiac and respiratory functions- thus to insure the physiological level, despite the brain's stopping its activity, and leading to an impossible social life- widely opened the door to new dilemmas that continue to be active topics for debates. The starting point was the necessity to find a new way of defining death, adequate for the remarkable progress in medicine. It is due to this progress that in some cases the traditional criterion of defining death, which is the cessation of heart and respiratory activity, has become inadequate and impractical. Suddenly, the medical world finds itself caught in its own virtuousness (10). The way out, not completely though, seems to be the introduction of the term brain death. Ever since this moment, in 1968[1], the concept of brain death triggered a multitude of medical, ethical, judicial and social problems. The fact that its introduction lead to such controversy on all aspects for over 40 years shows that a unique answer and solution are mere illusions (11).

As well as the attempt to solve the issue of defining death on the new background created by the progress in the reanimation field, the concept of brain death came up just in time to allow harvesting for transplant organs. The connection between the two events is more than obvious (12).

Were we to follow the temporary evolution of organ transplant and defining brain death, it would be clear that their development was parallel, as a consequence of progress in science and medical technology, but without any mutual conditioning. It was only in the '60s, when the first successful transplants are performed, using organs from dead donors, that the connection between the two is noticed (13).

The introduction of the brain death concept one year after the first successful heart transplant was considered by some authors to be the identification of a utilitarian solution meant to solve a problem both medical and social that was becoming ever more acute-the reduced number of transplant organs. However, this approach carried the risk of attempting for a definition of death according to necessity and not to scientific truth. Furthermore, there was the risk of transforming patients in a state of brain death into sheer instruments for reaching other people's targets.

Initially, brain death was the equivalent of the death of the entire brain. Subsequently, some authors affirmed that the death of the brain stem equals brain death since it involves the disappearance of the integrative functions (respiration, cardiac activity), in which case the cortical activity is no longer sustainable. As a consequence of the organ crisis, the notion of imminent cerebral death is introduced, in which are included those who do not meet all the criteria for brain death (13, 14).

Imminent brain death is characterized by complete loss of cortical functions and progressive weakness of brain stem functions. It is considered that they represent potential organ donors, for they are in a state of profound coma, as a consequence of massive and irreversible cerebral lesions of unknown origin; they depend on mechanic ventilation and have at least 3 abol-

[1] The concept of Cerebral Death was elaborated in 1968 by the Ad Hoc Committee of the Harvard Medical School. The criteria offered by this committee were three clinical signs: absence of visible reaction to external stimuli, absence of breathing and of spontaneous muscular movement for at least 1h, absence of reflexes (pupil, cornea, etc) and a paraclinical sign: the flat EEG line for at least 10 minutes.

ished brain stem reflexes (15).

Each of these concepts was supported by some researchers and fought by others with more or less relevant arguments.

BRAIN DEATH - THE CONTROVERSY CONTINUES…

Those who support the concept of whole brain death consider the brain to be the integrative unity of the organism. Its death will shortly lead to the disintegration of the human body as a whole and to the inevitable settling of death. This argument implies that heart failure is inevitable and that it happens soon after the ending of brain activity. Despite all this, in the case of some brain dead patients, a part of the integrative functions are kept (i.e. some automatic movements due to medullar reflexes).

In this context, the brain is simply a modulator, and not the central integration unity. Also, the patients with high cervical lesions have the same lack of integrative unity and yet they are not declared deceased. All the more so, brain death doesn't actually stand for the death of the entire brain, since research has shown that some brain dead patients recorded maintained functionality of certain brain areas, such as the secretion of antidiuretic hormone. Those who support the concept of brain death do not deny this reality, but demonstrate that the areas still functional are not essential for carrying out the brain's integrative functions (13).

The assumption that heart failure is unavoidable soon after brain death contradicts clinical experience, as there have been cases when spontaneous heart blocking in brain dead patients occurred no sooner than days or weeks after the end of cerebral activity (16).

The ones supporting the concept of brain stem death start from the idea that death is the irreversible loss of consciousness and of the capacity to breathe, shortly followed by the cessation of spontaneous heart beats.

Showman attacks this concept, claiming that the anatomic substrate necessary to express consciousness is maintained in the case of patients with massive, irreversible lesions of the brain stem, but with the integrity of brain hemispheres. Anatomic integrity is an argument for maintaining the brain functions; therefore one cannot have the certainty of lack of consciousness. In order to support this argument and to contradict the identification of the brain stem death with the death of the organism, there are patients in a vegetative state, with loss of consciousness, and patients with high cervical lesions, lacking the ability to spontaneously breathe; however, neither the former nor the latter are considered deceased (15, 17).

Higher brain death represents the irreversible loss of consciousness, considered to be the major attribute of human life. It is associated with the notion of imminent brain death, defined as the total loss of cortical functions, coming from the progressive weakness of the brain stem functions. In order to measure the degree brain affection, the FOUR (Full Outline of Un Responsiveness) score is used; it is calculated based on eye movement responsive to stimuli, motor response, brain stem reflexes and spontaneous breathing. Those who stand against this concept show that imminence is not similar to the event per se, and thus, the vegetative patients are not considered deceased, although they suffer from loss of consciousness (18, 19).

Out of all these concepts that came to be as a consequence of the need to identify the optimum moment for harvesting viable

organs for transplant, only the one of whole brain death is accepted in most countries; it is considered that just the patients with both the brain stem and the cerebral hemispheres destroyed are actually in a state of brain death and can thus be declared dead.

Despite all this, from a physiological point of view death is a process that cannot be reduced to one moment only. Thinking of death as a progressive process, between the emergence of brain death and the ending of all functions with the loss of the integrity of organs, we can at the most appreciate how far a certain moment is compared to the beginning or the ending of this process (20).

Referring to this aspect, Shewmon even builds a parallel from the point of view of life and the individual's identity; one between the period of time stretching from brain death and organism death and the time covered by the fetus from the moment of conceiving until birth (15).

Vital functions do not all collapse at the same moment, since in ICU (intensive care unit) some of them can be artificially maintained as a result of the development of resuscitation techniques and also that of life support. This is what makes the outline of clear and valid criteria for declaring the time of death very difficult.

The increasing need for transplant organs on the one hand, and the possibility of harvesting organs exclusively from deceased-declared persons, on the other hand, have forcefully lead to making arbitrary decisions regarding the setting of the exact time of death along the process of "losing life".

Seeing death as a process, harvesting organs from people in stages preceding death (but before all the criteria for its diagnosis are met) is one of the key elements of the ethical debate concerning the establishment of the exact time of death. It thus becomes essential to protect the person that is still alive, for the harvesting vital organs actually represents the moment of death (21).

In terms of these medical concepts and ethical principles, two polar opinions have been structured. On the one hand, cerebral death is seen as an artificially created term, requested by the increasing need for transplant organs; this term cannot be fully identified with the death of the individual. On the other hand, the artificial support of the respiratory and cardio-circulatory functions for a limited period of time in the case of a patient diagnosed with cerebral death does not mean his survival, but merely creating the conditions necessary for the harvesting of transplant organs from a corpse (5, 22).

This controversy has been lasting for over 40 years, in which time some of those who advocate for one of the opinions (for instance, Shewmon initially defended the central role of the brain and later on changed his position to that of considering the clinical signs of cerebral death as potential effects of serious lesions, including medullar shock). All these lead to yet another argument for the fact that there is no unique answer to this matter.

However, society holds its reserves in considering someone in a state of brain death as actually dead, mainly because of the light this casts upon the clear definition of death (22). Were we to consider organ transplant, ceasing the medical care of someone considered dead might lead to the impossibility of harvesting certain organs such as the heart, which might cause prejudice to potential receivers and deprive them of a surviving chance. This approach also has implications from the point of view of human dignity (at least for what it was, if not for what it is at that precise moment!),

given that the patient in the state of cerebral death is declared dead, whereas his body is still kept alive, deprived both of the rights of a living person and those of a deceased. The artificial support of vital functions is obtained by means of aggressive treatments aiming exclusively at preserving the organs to be transplanted to another person/ other people. The one who actually benefits this medical maneuver is not the one is the state of brain death, with no chance of surviving, but the one who might receive his organs. In this case, we might consider the idea of an abuse or of exploitation of a defenseless body to the benefit of another individual.

Art. 3 from the universal declaration of human rights guarantee each human being the right to life; in the case of euthanasia we can even speak of a human right to death. What can be appealed to in the case of a neither dead nor alive human ? Does a cerebrally dead still have the right to an identity ? (23).

Taking into account the fact that brain death and somatic death may occur in different moments in the case of the same patient and the fact that between the end of cardio-respiratory activity and that of cerebral activity there may be a period varying from hours to days, it is essential to accurately decide when the person can be declared dead, with all the ensuing consequences.

In Romania, judicially speaking, death is defined in the 95/ 2006 Act referring to health reform, where the matter of organ transplant is mentioned and brought under regulation. In title VI chap. II regarding "Donation and donor of organs, tissues and human cells", art 147, align. 1, the deceased donor is defined as the person that was found to have ceased cardio-respiratory activity, nonresuscitable and irreversible (somatic death), and in align. 2 of the same article, the deceased donor with cardiac activity is defined as the person that was observed to have irreversible cessation of all brain functions (brain death) (24).

It is thus decided that organs may be harvested both from those in a state of brain death and from the ones with nonresuscitable and irreversible cardio-respiratory cessation, as they are declared dead.

In the light of these aspects, we can conclude that both medically and legally, brain death is considered to be a person's time of death. This conclusion influences all the judicial consequences as to the ending point in the civil capacity (25).

Another issue rising from the acceptance of brain death as the end of someone's life is identity. Personal identity was defined keeping in mind two aspects: physical continuity (same body, same brain) and psychological continuity (same memories, same character). J. Locke says that the second perspective is necessary, considering memory and consciousness to be definitive for man, and Bernard Williams claims that body identity is a condition necessary for the idea of identity. The moral argument may lead only to the human being dignity that needs to be respected and that should be protected by the right to identity. Once the individual has lost the functions that define a human being- feelings, consciousness, memory etc- it is only moral to have his dignity respected, if not for what he is at the very moment, at least for what he was all his life (25).

CONCLUSIONS

Making the difference between the death of a person (also at a mental and social level) and the death of the biological

body may lead to a different interpretation concerning the definition of death and therefore of the moment it is generated, according to the criteria is uses. The concept of cerebral death keeps triggering controversy, despite the fact that in the case of the traditional definition of death, as the irreversible cessation of the cardio-respiratory activity, establishing the time of death raises no medical, ethical or legal issues. Medically speaking, the biological organism is still alive as long as the heart continues to beat, conditioned, however, by artificial respiration. Nonetheless, according to the definition of the human being from a legal and ethical perspective, a person is declared deceased when all the levels definitive of his or her life no longer exist. In these situations, it is also impossible to preserve the biological level unless the essential biological functions are artificially supported. The controversy of brain death actually springs from the identification of this concept with that of biological death of the person; what differentiates the two is made by whether the mental features in the definition and individualization of the human life and death are accepted or not.

Regardless of which of the two opinions we advocate, we are facing a dilemma, for they are two indisputable facts: on the one hand, organ transplant helps save lives, and on the other no one can be killed and neither can his death be rushed by or for harvesting organs. All this considered, we return to the dilemma of defining the death of the individual: we define death, as it has been done for hundreds of years, as the moment of cessation of cardio-respiratory function, which will lead to the loss of many lives that might be saved by transplant or we go on manipulating the borderline between life and death, with the risk of defying the right to life.

ACCREDITATION

CEDRUS DEODARA NEEDLES – ANTIBACTERIAL ACTIVITY AGAINST FOOD-BORNE BACTERIA

Cedrus deodara, also known as Himalayan cedar, has been widely used as food and drug in China. The needles have nutritional value due to a high content in proteins, vitamins and minerals. This study reports the antibacterial activity of a water-soluble extract from needles on five food-borne bacteria (*Escherichia coli*, *Proteus vulgaris*, *Staphylococcus aureus*, *Bacillus subtilis*, *Bacillus cereus*). The extract showed a potent antibacterial activity with minimum inhibitory concentrations (MICs) from 0.78 to 12.5 mg/ml; the minimum bactericidal concentrations (MBCs) were in the range of 1.56-25 mg/ml. The mechanism of action was investigated by transmission electron microscope; changes of external morphological features of *Staphylococcus aureus* (broken cell walls and membranes, release of cytoplasm) were revealed. The main constituent in the extract, shikimic acid, was isolated and was found to be responsible for the antibacterial activity of the extract. Taken together, these results suggest that *Cedrus deodara* needles are an important source of natural antibacterial agents with potential uses in both food and pharmaceutical industry. (Zeng W-C, He Q, Sun Q, Zhong K, Gao H. Antibacterial activity of water-soluble extract from pine needles of *Cedrus deodara*. *Int J Food Microbiol* 2012; 153: 78-84).

FUNCTIONAL ELECTRICAL STIMULATION EFFECT ON THE MOTOR PERFORMANCES IN PARKINSONIAN PATIENTS (Abstract): Parkinson's disease (PD) is a neurodegenerative disease involving dopaminergic, cholinergic, glutaminergic, serotoninergic and noradrenergic neurons, having as clinical manifestations both motor and non-motor symptoms. Functional electrical stimulation (FES) is a complementary therapy that can improve the motor disabilities (i.e. bradykinesia, hypokynesia and the motor block/ "freezing"). **The aim** of this study is to assess, by clinical scales and tests, the influence of FES on motor symptoms in Parkinsonian patients and to establish the differences in motor learning with healthy subjects. **Material and methods:** 26 PD patients and 15 healthy volunteers were included in the study. The two groups of subjects were clinically assessed at two different points in time: before and after ten consecutive days of FES exercise for 30 min/day on the most affected/ less skilful upper and lower limb. **Results:** All of the clinical tests revealed bilaterally improvements in both groups, mainly in PD patients group, even if the FES application was unilaterally. **Conclusions:** Unilateral peripheral electrostimulation improves bilaterally motor performances due to an interhemispheric transfer called "cross education". This phenomenon seems to be more pronounced in Parkinsonian patients because of the alteration of cortical inhibition. **Key words:** PARKINSON'S DISEASE, FUNCTIONAL ELECTRICAL STIMULATION, MOTOR PERFORMANCES, CORTICAL INHIBITION

Boala Parkinson (BP) este o maladie neurodegenerativă multifocală progresivă, caracterizată prin simptome motorii şi nonmotorii, care pot duce în timp la un grad important de dizabilitate (1). Procesul degenerativ afectează în special neuronii dopaminergici din substanța neagră mezencefalică şi nucleii bazali. Evoluția bolii cunoaşte trei stadii (preclinic, premotor şi motor), din care ultimul este patognomonic (2). Afecțiunea devine manifestă când numărul de neuroni dopaminergici ajunge la circa 20%, iar cantitatea de dopamină scade la jumătate față de normal. Simptomele motorii pot fi ameliorate prin tratament dopaminergic, dar şi prin metode terapeutice complementare: stimulare cerebrală profundă (DBS), stimulare magnetică repetitivă (rTMS), stimulare electrică funcțională (FES). Există numeroase studii referitoare la stimularea cerebrală (electrică sau magnetică), însă datele privitoare la aplicațiile FES în boala Parkinson sunt puține (3).

Studiul de față îşi propune evaluarea

efectului stimulării electrice funcționale asupra bradikineziei şi a fenomenului de *"freezing*" (blocaj motor) la un grup de pacienți parkinsonieni, respectiv stabilirea diferențelor de învățare motorie în raport cu un grup de subiecți sănătoşi.

MATERIAL ŞI METODE

Studiul este de tip analitic intervențional - trial clinic controlat randomizat. În lotul test au fost incluşi 26 de pacienți parkinsonieni, recrutați din Clinica de Neurologie a Spitalului Clinic de Recuperare Iaşi în perioada ianuarie 2011-ianuarie 2012. Lotul martor a fost alcătuit din 15 voluntari sănătoşi (V). Atât subiecții bolnavi, cât şi cei sănătoşi, au fost informați de posibilitatea participării la studiu şi şi-au exprimat acordul prin semnarea consimțământului aprobat de Comisia de Etică a Spitalului.

Selecția pacienților s-a realizat pe baza unor criterii de includere, şi, respectiv, de excludere.

Criterii de includere:

- vârsta între 30 şi 85 de ani;
- boală Parkinson idiopatică, stadiile I-III Hoehn-Yahr, controlată medicamentos; fază "on" la momentul examinării;
- status cardio-vascular şi neurologic stabil;
- nivel cognitiv suficient de bun pentru a înțelege principiul de funcționare şi modul de aplicare a dispozitivelor de stimulare electrică funcțională.

Criterii de excludere:

- parkinsonism atipic, secundar sau din alte boli neurodegenerative;
- patologie cerebrală şi/sau medulară cu interesarea sistemului piramidal şi/sau extrapiramidal;
- epilepsie netratată sau refractară;
- *pacemaker* cardiac;
- leziuni ale nervului radial şi/sau sciatic popliteu extern (SPE);
- afecțiuni osteo-articulare sau dermatologice la nivelul antebrațului şi gambei propuse pentru FES;
- boli cardio-vasculare grave;
- demență.

Într-o primă etapă, fiecărui participant la studiu i s-a întocmit o fişă cu următoarele date: sex, vârstă, membrul superior (MS) cel mai afectat (în cazul pacienților) sau MS mai puțin abil (în cazul voluntarilor).

Evaluarea inițială a pacienților cu BP s-a realizat prin stabilirea stadiului Hoehn-Yahr, aprecierea nivelului de independență în activitățile din viața cotidiană pe scala Schwab & England, evaluarea mersului prin scorul Tinetti Gait, aprecierea stării generale pe scala Webster Rating şi a statusului motor prin scorul UPDRS motor (4).

La membrele superiore s-au aplicat *testul de închidere şi deschidere a pumnului* (numărând de câte ori pe minut subiectul execută aceste mişcări) şi *nine hole peg test-ul/9-HPT* (măsurând timpul în care subiectul umple 9 găuri cu 9 cuie de lemn şi apoi le scoate).

La membrele inferioare (MI) s-au observat inițierea şi fluența mişcării utilizând *5m-timed-up-and-go test (5m-TUG)*; din poziția şezând, subiecții au fost invitați să se ridice de pe scaun, să parcurgă distanța de 5 metri, să se întoarcă şi să revină la poziția inițială. S-au notat următorii parametri: viteza de mers (= 10 m/timp); indicele energetic [PCI= (FC în mers - FC în repaus)/viteza x 60m/min, unde PCI= Physiological Cost Index, FC=frecvența cardiacă]; lungimea medie a pasului (P= 10 m/nr. paşi); cadența (=nr. paşi/timp). Aceleaşi teste au fost aplicate şi voluntarilor sănătoşi.

După această evaluare, subiecții din cele două loturi au urmat un program de FES

timp de 10 zile, câte o şedinţă de 30 min/zi, la MS cel mai afectat/mai puţin abil şi la MI de aceeaşi parte. Electrozii au fost plasaţi pe traiectul nervului radial la MS şi pe traiectul nervului peronier comun (SPE) la MI. În vederea stimulării s-au utilizat două tipuri de aparate: Odstock Microstim 2v2 pentru MS şi Odstock Dropped Foot Stimulator (ODFS3) pentru MI, procurate de la centrul specializat din Salisbury, Anglia, şi avizate de Ministerul Sănătăţii din România. Parametrii curentului utilizat au fost: amplitudinea= 10-100 mA, reglabilă, cu 1 kΩ impedanţă de ieşire, durata pulsului= 300 μs pentru Microstim 2v2 şi 350 μs pentru ODFS3, frecvenţa stimulării= 40 Hz, forma de undă= asimetrică bifazică.

La sfârşitul celor 10 zile de antrenament, participanţii au fost reevaluaţi prin aceleaşi scale şi cu aceeaşi baterie de teste, iar valorile obţinute s-au comparat cu cele măsurate înainte de stimulare.

Prelucrarea statistică a datelor s-a realizat în programul SPSS 17 aplicând testele statistico-matematice p, χ^2, t.

REZULTATE

Ponderea subiecţilor de sex masculin a fost uşor mai crescută în lotul de parkinsonieni (57,7%), însă distribuţiile de frecvenţă nu prezintă diferenţe semnificative faţă de lotul voluntari sănătoşi (33,3%) (χ^2=4,49; GL=3; p=0,214). Pe cazuistica studiată nu s-au evidenţiat diferenţe semnificative între sexe ale vârstei medii. Totuşi, vârsta medie a lotului de pacienţi parkinsonieni a fost semnificativ mai mare faţă de lotul de voluntari sănătoşi (p=0,012) (tab. I).

TABELUL I

Indicatori statistici ai sexului şi vârstei pe loturile studiate

Lot	Sex (F/B)	N	Vârsta medie (ani)	Deviaţie standard	Eroare standard	Diferenţe între sexe	Diferenţe faţă de voluntari
Voluntari sănătoşi	F B Total	10 5 15	59,60 53,20 57,47	11,25 14,27 12,21	3,56 6,38 3,15	t=0,953 p=0,358	-
Pacienţi parkinsonieni	F B Total	11 15 26	66,45 66,40 66,42	7,79 10,75 9,43	2,35 2,77 1,85	t=0,014 p=0,989	t=2,626 p=0,012

Influenţa stimulării electrice funcţionale asupra scorurilor diferitelor scale se poate observa în fig. 1. FES nu a modificat *stadiul Hoehn-Yahr* (I-III) de evoluţie a bolii la nici unul dintre pacienţi, media lotului fiind 2,2. Valorile medii obţinute pe *scala Schwab & England* (0-100%) au crescut semnificativ după stimulare electrică funcţională de la 73% la 80% (t=2,16; p<0,05). *Scorul mediu Tinetti Gait* (0-12) a înregistrat o uşoară creştere după FES de la 7,6 la 9,1 (t=1,91; p>0,05). Valorile medii obţinute pe *scala Webster Rating* (0-30) au scăzut după FES de la 14,2 la 11, însă descreşterea nu a fost semnificativă din punct de vedere statistic (t=1,97; p>0,05). Scorul mediu UPDRS motor (0-108) a înregistrat o uşoară descreştere după FES, de la valoarea medie de 37,9 la 31 (t=1,71; p>0,05).

Modificările parametrilor clinici la testele aplicate membrelor superioare. Înainte de FES, la MS cel mai afectat, valorile medii la testul de închidere-deschidere a pumnului au fost semnificativ mai reduse la parkinsonieni comparativ cu voluntarii sănătoşi (tab. II).

După stimulare, viteza s-a îmbunătățit cu 37,8%, apropiindu-se de valorile înregistrate la voluntari (la care a crescut cu 16,5%). La MS controlateral nu s-au înregistrat diferențe statistic semnificative, nici înainte nici după stimulare, iar creşterea după FES a valorilor medii a fost de 18% la pacienții cu BP şi de 6,3% la subiecții sănătoşi.

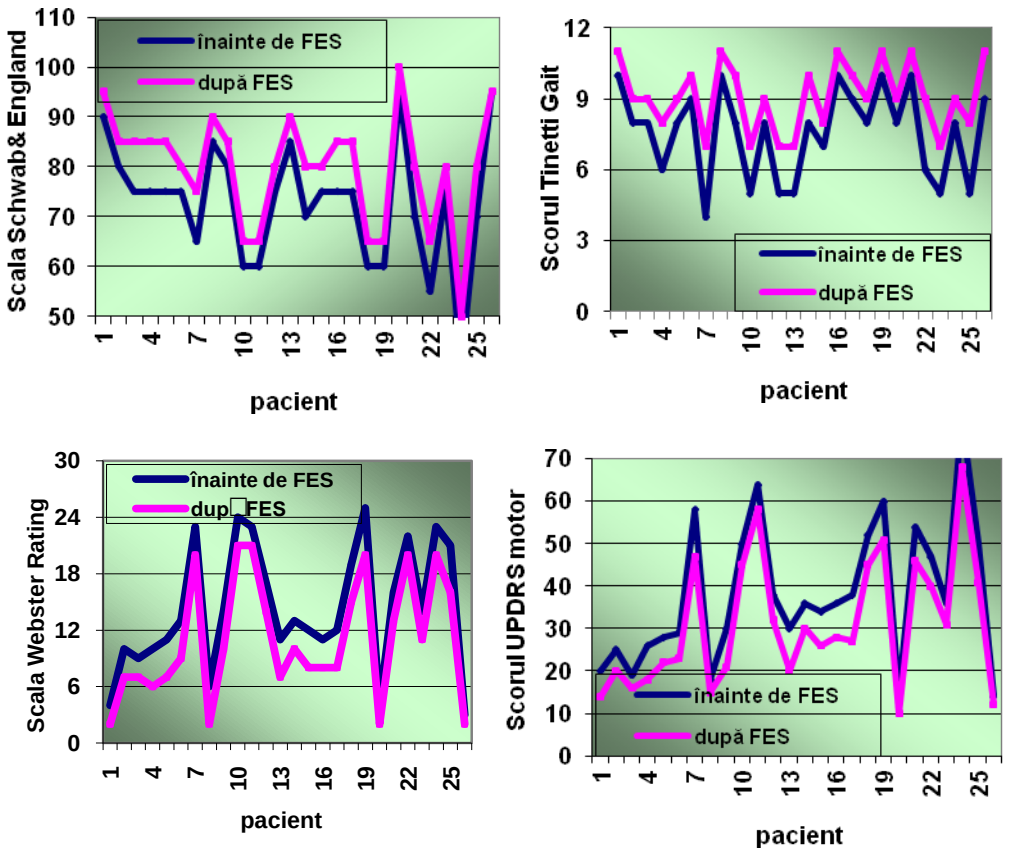

Fig. 1. Evoluția valorilor individuale în funcție de scala de evaluare

TABELUL II

Testul de închidere-deschidere a pumnului

Loturi		N	MS cel mai afectat/ mai puțin abil			MS controlateral		
			Medie (/min)	Deviație standard	Eroare standard	Medie (/min)	Deviație standard	Eroare standard
Înainte de FES	BP	26	50,96	17,67	3,46	60,00	18,31	3,59
	V	15	65,33	16,30	4,21	70,87	19,06	4,92
După FES	BP	26	70,24	20,65	4,51	70,81	16,99	3,71
	V	15	76,08	18,06	5,21	75,33	20,63	5,96

Valorile medii obținute la testul 9-HPT au fost semnificativ mai mari la pacienții cu BP comparativ cu subiecții sănătoşi, atât înainte cât şi după FES. Totuşi, prin stimulare, timpul de realizare a testului a scăzut cu 29,7% pentru MS stimulat şi cu 18,4% pentru MS controlateral (în raport cu 8,2% şi, respectiv, 6,7% la voluntari) (tab. III).

Parametrii înregistrați la testul de mers au cunoscut o ameliorare post-stimulare mai evidentă în cazul pacienților parkinsonieni, cu excepția lungimii pasului care a crescut mai mult la subiecții sănătoşi (fig. 2).

TABELUL III

Nine Hole Peg Test (9-HPT)

Loturi		N	MS cel mai afectat/ mai puțin abil			MS controlateral		
			Medie (sec)	Deviație standard	Eroare standard	Medie (sec)	Deviație standard	Eroare standard
Înainte de FES	BP	26	47,87	36,69	7,19	35,15	18,31	3,59
	V	15	25,20	3,68	0,95	25,13	3,04	0,79
După FES	BP	26	33,67	11,65	2,54	28,69	6,48	1,41
	V	15	23,13	1,55	0,45	23,46	2,70	0,78

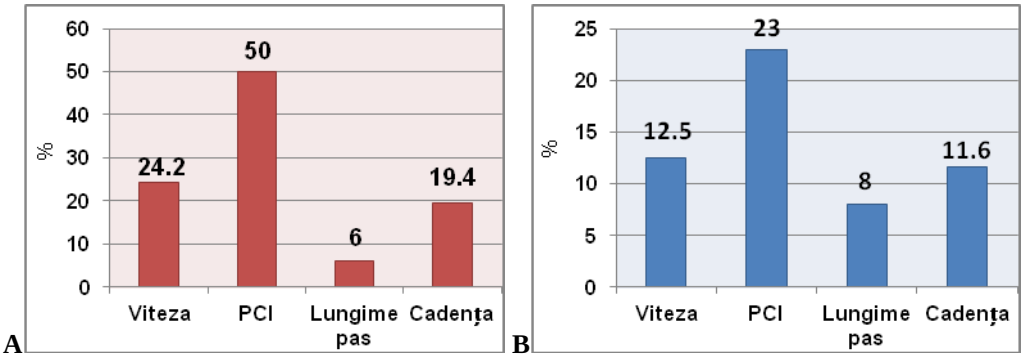

Fig. 2. Evoluția indicatorilor statistici la 5m-TUG, după FES
A.la pacienții parkinsonieni, B. la subiecții sănătoşi

DISCUȚII

În concordanță cu statisticile din literatura de specialitate, în lotul de pacienți parkinsonieni vârsta medie a fost peste 60 de ani (66,4 ani), cu o uşoară predominanță masculină (57,7%).

Testele clinice au pus în evidență o ameliorare semnificativă ($p<0,05$) a bradi- şi hipokineziei la pacienții cu BP şi o îmbunătățire a performanțelor motorii la subiecții sănătoşi după stimulare electrică funcțională. Creşterea vitezei de realizare a testelor a fost bilaterală în toate loturile, mai ales în grupul cu BP, deşi stimularea a fost unilaterală.

Studii recente de rezonanță magnetică funcțională (fMRI) au arătat că aplicarea electrostimulării pe muşchii extensori şi flexori ai pumnului la voluntarii sănătoşi determină activarea cortexului motor pri-

mar controlateral, a ariei primare somatosenzoriale şi a cortexului premotor controlateral, precum şi a cerebelului ipsilateral, a ariei secundare somatosenzoriale bilateral, a ariilor motorii suplimentare şi a cortexului cingulat anterior bilateral (5). Mai mult decât atât, se pare că FES este capabilă să modifice excitabilitatea la nivelul conexiunilor interemisferice şi implicit echilibrul excitație-inhibiție (6). Totodată, antrenamentul fizic al unui membru se însoțește de mărirea forței de contracție în membrul opus, neantrenat, prin diminuarea inhibiției corticospinale şi existența unui proces de transfer interemisferic, cunoscut sub numele de "cross education" (7, 8). Deşi au efecte supraspinale diferite, stimularea electrică şi kinetoterapia pot creşte, ambele, forța de contracție la nivelul muşchiului omolog din membrul controlateral (8).

Perioada de linişte corticală, un marker al inhibiției intracorticale obținut prin stimulare magnetică transcraniană, este mai scurtă la parkinsonieni comparativ cu subiecții sănătoşi, durata sa fiind mai mică pe emisfera opusă hemicorpului mai afectat (9). Inhibiția interemisferică şi facilitarea intracorticală sunt de asemenea reduse la pacienții parkinsonieni (10). Probabil că alterarea circuitelor inhibitorii constituie substratul ameliorării bilaterale în urma FES a statusului motor la pacienții cu BP.

CONCLUZII

Cercetarea noastră a urmărit evaluarea aportului stimulării electrice funcționale în ameliorarea simptomelor motorii din boala Parkinson. Aplicarea unilaterală a stimulării neuromusculare a determinat o creştere a mobilității membrelor stimulate, dar şi a membrelor controlaterale, nestimulate. Acest efect a fost mai important în cazul pacienților parkinsonieni comparativ cu voluntarii sănătoşi.

NEUROPAD® TEST IN EVALUATION OF DIABETIC FOOT (Abstract): **Aim.** Diabetic neuropathy (DN) is the main cause of foot ulceration. One of the earliest modifications is the loss of normal sudomotor function, a sign of autonomic neuropathy. The aim of this study is to evaluate sudomotor dysfunction using a new tool (Neuropad®) in diabetic patients with foot ulceration. **Material and methods.** We included 58 diabetic patients with foot ulceration admitted in 2010 in the Clinical Center for Diabetes, Nutrition and Metabolic Diseases. We collected data regarding age, gender, type and duration of diabetes, glycated hemoglobin (HbA1c), history of amputations and duration of hospital admission. Peripheral neuropathy was evaluated through the Neuropathy Disability Score (NDS) and autonomic neuropathy was tested through Neuropad®. **Results.** 95% of patients had NDS $\geq$ 6, among which 76% had also positive Neuropad® test. Patients with both peripheral and autonomic neuropathy had longer duration of diabetes (p=0.027) but similar HbA1c as patients with only peripheral neuropathy (p=0.09). The former also had longer duration of current admission (p=0.022) and a higher percentage of these patients had history of amputations (p=0.041). **Conclusions.** Neuropad® is a reliable, easy to use test for the diagnosis of autonomic neuropathy, which puts patients at greater risk for foot ulceration and amputation

Neuropatia diabetică (ND) are un important impact negativ asupra calității vieții şi supraviețuirii la pacienții cu diabet, iar componenta sa autonomă (NDA) este una dintre complicațiile cronice cele mai puțin diagnosticate şi înțelese (1). Evaluarea afectării nervoase în ND este importantă pentru a defini grupurile aflate la risc de a dezvolta pierderea sensibilității, durere şi ulcerații la nivelul piciorului. Teste clinice simple pentru evaluarea deficitelor neurologice includ scorul de neuropatie (Neuropathy Disability Score – NDS) (2), pragul de percepție vibratorie sau testarea cu monofilamentul Semmes-Weinstein pentru a defini neuropatia severă şi deci riscul de ulcerație (3).

NDA poate fi evidentă clinic sau de natură subclinică şi poate afecta unul sau mai multe organe sau sisteme, fiind cardiovasculară, gastrointestinală, sudomotorie, oculară etc. (4). Manifestările clinice de NDA sunt evidente după o perioadă îndelungată de evoluție a diabetului, în timp ce disfuncția subclinică poate exista chiar la 1 an de la diagnostic la pacienții cu diabet zaharat (DZ) tip 2 (5). În general, NDA centrală este evaluată prin cercetarea variabilității frecvenței cardiace, iar cea periferică prin

teste ale funcţiei sudomotorii. Simptomele NDA sudomotorii sunt reprezentate de hiperhidroză în partea superioară a corpului (legată uneori de alimentaţie, fiind cunoscută sub denumirea de „transpiraţie gustativă") şi reducerea secreţiei sudorale, uneori până la anhidroză, în jumătatea inferioară, intoleranţă la cald. Afectarea autonomă sudorală la nivelul picioarelor va duce la piele uscată, producerea de fisuri, ceea ce reprezintă un factor de risc pentru ulceraţii ulterioare la acest nivel (6).

Testele utilizate pentru evaluarea funcţiei sudomotorii relevă extensia, distribuţia şi localizarea deficitului activităţii simpatice colinergice, dat fiind faptul că fibrele postganglionare simpatice ce inervează glandele sudoripare secretă acetilcolină. Aceste teste includ testul cantitativ sudoral axono-reflex (quatitative sudomotor axon reflex test - QSART), amprenta sudorală, testul termoreglării (thermoregulatory sweat test – TST) şi reacţia simpatică la nivelul pielii. QSART implică iontoforeza unui agonist colinergic pentru a măsura răspunsul sudomotor mediat de reflexul de axon. Amprenta sudorală necesită existenţa unui mulaj de plastic sau silicon ce captează secreţia sudorală ca răspuns la iontoforeza unui agonist colinergic. TST evaluează distribuţia sudoraţiei printr-o modificare de culoare a unui indicator aplicat pe piele după expunerea la raze infraroşii. Reacţia simpatică la nivelul pielii sau potenţialul autonom periferic de suprafaţă generat de glandele sudoripare poate fi măsurat cu ajutorul electrozilor conectaţi la un electromiograf (7). Toate aceste teste necesită aparatură complexă şi scumpă, fiind dificil de utilizat de rutină.

Ca instrument de screening al disfuncţiei sudorale dispunem la ora actuală de testul comercial Neuropad®, recent propus ca o metodă simplă de diagnostic a disfuncţiei sudomotorii şi implicit a NDA la nivel periferic, la pacienţii cu DZ (8), cu reproductibilitate foarte bună (9). Consensul de la San Antonio (10) recomanda efectuarea testelor pentru NDA cardiovasculară, considerând că doar acestea erau standardizate şi potrivite pentru screening-ul şi monitorizarea progresiei NDA. Mai recent, Asociaţia Americană de Diabet (ADA) recomandă şi examinarea funcţiei sudomotorii pentru detecţia NDA (11). Testul Neuropad® este un plasture impregnat cu soluţie de clorură de cobalt, care îşi schimbă culoarea în funcţie de starea de hidratare a zonei de tegument pe care este aplicat, de la albastru la roz, dacă sudoraţia şi deci funcţia simpatică colinergică este normală (8). Aplicarea se realizează pe o zonă de tegument curată, în condiţii de confort termic, iar citirea virajului culorii se face după 10 minute. Testul poate fi autoadministrat de către pacient (ceea ce reprezintă un avantaj) şi se recomandă a fi efectuat cel puţin odată la 6 luni. Un rezultat anormal al testului impune evaluarea detaliată a celorlalţi factori de risc. (6).

Scopul acestui studiu a fost de a evalua prezenţa disfuncţiei sudomotorii printr-un instrument nou - plasturele Neuropad® la pacienţii cu DZ şi cu ulceraţie pe fond neuropat.

MATERIAL ŞI METODE

Lotul de studiu a fost format din pacienţii internaţi în Centrul Clinic de Diabet, Nutriţie şi Boli Metabolice pe parcurul anului 2010 cu diagnostice în relaţie cu "piciorul diabetic". Au fost excluşi din studiu pacienţii cu diagnostic de arteriopatie obliterantă a membrelor inferioare.

Pentru fiecare pacient s-au înregistrat următoarele date: sex, vârstă, tipul de diabet zaharat, durata diabetului, valoarea he-

moglobinei glicate (HbA1c), istoricul de amputaţii, durata actualei spitalizări.

Neuropatia periferică a fost diagnosticată pe baza scorului de neuropatie (Neuropathy Disability Score - NDS) ≥ 3. NDS este un sistem de clasificare a neuropatiei periferice care se bazează pe suma unor semne şi simptome prezentate de pacient la nivelul ambelor membre inferioare: reflexele achiliene, percepţia vibraţiei evaluată cu diapazonul, sensibilitatea la durere şi sensibilitatea la temperatură cu Tip-therm.

Componenta de neuropatie vegetativă a fost testată cu Neuropad®. Pacienţii au fost aşezaţi în decubit dorsal, fără pantofi şi şosete pentru cel puţin cinci minute înainte de testare. Plasturele cu cobalt a fost aplicat la nivelul capului metatarsianului unu sau doi. Atunci când pe locul de amplasare exista piele hipercheratozică sau o ulceraţie, locul de aplicare a fost schimbat cu capul celui de al 5-lea metatarsian. După zece minute a fost evaluat rezultatul: lipsa de schimbare de culoare de la albastru la roz, sau schimbare incompletă (albastru şi roz mixt) au fost considerate a corespunde unui test de screening pozitiv, însemnând pierderea sudoraţiei şi, prin urmare, disfuncţie autonomă. Dimpotrivă în cazul în care cardul a devenit complet roz, testul a fost considerat normal.

Analiza statistică a folosit testul $\chi 2$ pentru variabile categoriale şi testul t Student pentru variabilele continue.

REZULTATE

În anul 2010, în Centrul Clinic de Diabet, Nutriţie şi Boli Metabolice au fost internaţi 90 de pacienţi cu diagnostice în relaţie cu "piciorul diabetic". Dintre aceştia, 32 prezentau diagnosticul de arteriopatie obliterantă a membrelor inferioare. Astfel, pe baza criteriilor de includere şi excludere, s-a format un lot de studiu de 58 de pacienţi, dintre care 43 sunt bărbaţi (74%). Vârsta medie ± DS în lotul studiat este de 60.2 ± 4.1 ani. Doar 5 pacienţi prezintă DZ tip 1 (8.6%), restul având DZ tip 2. Durata medie a bolii a fost de 13.9 ± 2.6 ani, iar media HbA1c a fost de 8.7 ± 1.1 %. 95 % dintre pacienţi au prezentat un scor de neuropatie (NDS) ≥ 6. Dintre aceştia, 42 de pacienţi (76 %) au prezentat test Neuropad® anormal (pozitiv). De asemenea 2 din cei 3 pacienţi cu scor de neuropatie (NDS) < 6 au prezentat test Neuropad® pozitiv. În total, 44 de pacienţi (75.8%) au prezentat test Neuropad® pozitiv, implicit neuropatie autonomă.

Am analizat 2 subloturi de pacienţi: sublotul A, format din pacienţi care prezentau numai neuropatie periferică, evaluată prin scor de neuropatie (NDS) ≥ 6, fără neuropatie autonomă (test Neuropad® normal), şi anume 21% dintre pacienţi (12 pacienţi) cu sublotul B, format din pacienţi care prezentau ambele forme de neuropatie, şi anume 72.4% dintre pacienţi (42 pacienţi).

Pacienţii din sublotul B au prezentat un scor de neuropatie (NDS) statistic semnificativ mai mare decât pacienţii din grupul A (p=0.043). De asemenea, pacienţii din sublotul B au prezentat o durată a diabetului statistic semnificativ mai mare (15.4 ± 2.1 ani) decât pacienţii din sublotul A (11.8 ± 2.5 ani), p=0.027. Nu au existat diferenţe semnificative statistic în privinţa valorilor HbA1c între cele 2 subloturi (p=0.09). Un procent semnificativ statistic mai mare dintre pacienţii din sublotul B au prezentat istoric de amputaţii (34.7%), faţă de pacienţii din sublotul A (30.8%), p=0.041. De asemenea, durata spitalizării a fost semnificativ statistic mai mare la pacienţii din sublotul B (15.3 ± 1.03 zile) faţă de pacienţii din sublotul A (11.2 ± 1.6 zile), p=0.022.

DISCUȚII

Neuropatia periferică (senzitivo-motorie şi vegetativă) este principala cauză a ulcerației la picior la pacienții cu DZ. Una dintre primele sale manifestări este pierderea sudorației normale la picior, care are ca rezultat uscarea pielii şi riscul de fisură. Funcția sudomotorie are un rol protectiv deosebit de important, iar prezența NDA la nivel periferic, caracterizată prin anhidroză, reprezintă o verigă fiziopatologică importantă în apariția ulcerațiilor (12). Disfuncția sudomotorie subclinică poate să fie detectată precoce în DZ, chiar şi la subiecții cu viteză de conducere nervoasă normală (13). În consecință, identificarea pacienților la risc pentru ulcerații la nivelul piciorului utilizând metode simple şi de încredere are o relevanță clinică deosebită.

Quattrini et al. (14) au comparat rezultatele evaluării piciorului diabetic prin Neuropad® şi prin teste obiective ale neuropatiei somatice şi autonome, inclusiv densitatea intra-epidermală a fibrelor nervoase în biopsia cutanată, obținând că răspunsul anormal la testul Neuropad® s-a corelat cu NDS, sensibilitatea termică, cu simptomele de neuropatie şi cu variabilitatea frecvenței cardiace. De asemenea, densitatea fibrelor nervoase a fost semnificativ mai redusă la pacienții cu test Neuropad® anormal. Autorii concluzionează că testul Neuropad® este o metodă simplă pentru screening-ul pacienților cu ND.

Studiul lui Tentolouris et al. (15) a găsit că un test Neuropad® anormal se corelează cu prezența ulcerațiilor la pacienții cu diabet, sugerând că acest test poate fi inclus printre testele screening de prezicere a ulcerației piciorului. Şi în studiul nostru, majoritatea pacienților au prezentat funcție sudomotorie anormală (75.8 %). De asemenea, într-un alt studiu s-a arătat că 95% dintre pacienții cu ulcerații au prezentat anhidroză, evaluată prin Neuropad®, date similare cu evaluarea prin reacția simpatică la nivelul pielii, şi că valoarea NDS a fost mai mare la pacienții cu ulcerații (16). Valoarea predictivă a testului Neuropad® pentru ulcerații este similară cu utilizarea monofilamentului, percepția vibratorie şi NDS (15). Un alt studiu efectuat pe 154 pacienți cu DZ tip 2 în care ND a fost diagnosticată clinic utilizând NDS, a arătat că sensibilitatea pentru acest diagnostic a fost mai mare cu testul Neuropad®, comparativ cu pragul de percepție a vibrațiilor, dar specificitatea a fost mai mare în cazul celui de al doilea test. Astfel, testul Neuropad® pare a fi un instrument suplimentar util de diagnosticare a neuropatiei, deosebit de potrivit pentru screening şi auto-examinare, în DZ tip 2 (17). Mai mult decât atât, s-a demonstrat că testul Neuropad® a fost capabil să separe pacienții în grupuri cu diferite profile de risc general, inclusiv vârstă, durata DZ, prezența bolii vasculare coronariene şi/sau cerebrale, nefropatie şi retinopatie, precum şi să stratifice pacienții în grupuri cu diferite stadii de ND, evaluată prin simptome, diagnostic, NDS (18).

O potențială limitare clinică a testului Neuropad® ar putea fi reprezentată de intervalul de 10 minute necesar pentru citirea rezultatului. Un studiu recent sugerează că intervalul minim de timp pentru a defini un test Neuropad® ca fiind anormal poate fi 530 secunde (19). Ziegler et al. (20), într-un studiu recent, a găsit că în primul an de la diagnosticul de DZ, valoarea cut-off de citire a Neuropad® la 10 minute oferă o sensibilitate relativ mare şi o specificitate modestă pentru polineuropatie distală simetrică (PDS) şi pentru disfuncția de fibre mici, fiind potrivit ca instrument de screening, mai mult decât punctele de cut-off de

citire la 15 şi 20 minute. Spre deosebire de aceste date, un alt studiu demonstrează că valoarea cut-off de 15 minute, comparativ cu 10 minute, a arătat o specificitate mai bună pentru NDA cardiovasculară şi PDS, fără a diminua sensibilitatea, autorii concluzionând că este un instrument fiabil de diagnostic pentru ambele afecţiuni, deşi numai de precizie moderată, şi că extinderea perioadei de observaţie la 15 minute oferă o mai mare utilitate de diagnosticare (21). Papanas et al. (22) a evaluat relaţia dintre Neuropad® şi NDS la pacienţi cu DZ tip 2, ajungând la concluzia că timpul necesar pentru virajul culorii poate indica stadiul PDS, efectuându-se astfel un triaj al pacienţilor ce necesită îngrijiri de specialitate. Acelaşi autor (23), într-un studiu prospectiv, a găsit că dintre pacienţii cu DZ tip 2 cu NDS normal, dezvoltarea de neuropatie este semnificativ mai frecventă la cei cu Neuropad® anormal. Aceste rezultate sugerează un potenţial de utilitate al Neuropad® pentru diagnosticul precoce al neuropatiei în DZ tip 2.

Totusi, avantajul practic evident al acestui test este că pacientul poate să îl efectueze singur, inclusiv la domiciliu şi, mai mult decât atât, vizualizarea unui rezultat anormal va creşte gradul de conştientizare al riscului de ND şi ulceraţie (24).

În ciuda evoluţiei tratamentului prin implicarea echipelor multidisciplinare, ratele amputaţiilor majore rămân mai mari decât se doreşte, cu costurile aferente exorbitante. Pentru reducerea acestora este necesar să se crească efortul pentru prevenirea ulceraţiilor şi să se focalizeze atenţia pe prima etapă a cascadei evenimentelor prin detectarea precoce a neuropatiei periferice (25).

Mai multe studii au confirmat sensibilitatea testului cu monofilamentul Semmes-Weinstein în detectarea neuropatiei periferice. Este unanim acceptat că este cel mai simplu mod de testare şi de asemenea reproductibil (26). Cu toate acestea, este o evaluare care necesită colaborarea pacientului şi poate fi influenţată de către examinator, având o interpretare subiectivă. În schimb, testul Neuropad® este un mod obiectiv de testare, reproductibil şi uşor de executat. După cum a postulat Risse (27), cu cât fibra nervoasă este mai subţire, cu atât este mai precoce afectarea sa, iar, cum fibrele nervoase vegetative sunt nemielinizate, şi deci mai subţiri decât fibrele senzoriale, vor fi primele afectate. Acest lucru poate explica detecţia mai precoce a pacienţilor cu neuropatie periferică cu ajutorul testului Neuropad®, comparativ cu rezultatele obţinute cu monofilamentul Semmes-Weinstein, care aparent poate reprezenta un alt avantaj al primului.

CONCLUZII

În lotul studiat 95% dintre pacienţi au prezentat neuropatie periferică senzitivo-motorie (NDS≥6). La 76% dintre aceştia a fost găsită şi neuropatie autonomă, detectată prin test Neuropad® pozitiv. În plus 2/3 din pacienţii fără neuropatie periferică au prezentat neuropatie autonomă.

Pacienţii cu neuropatie periferică şi autonomă au avut o durată a diabetului mai mare, un istoric mai important de amputaţii şi un interval mai lung de spitalizare faţă de subiecţii care au prezentat numai forma periferică de neuropatie.

Având la dispoziţie testul Neuropad®, uşor de utilizat, am putut analiza şi componenta autonomă a neuropatiei, de obicei neobiectivată, şi astfel am putut individualiza un sublot de pacienţi la risc mai mare de a dezvolta ulceraţii cu o evoluţie mai îndelungată.

NOUTĂȚI

DEFICITUL DE VITAMINA D ŞI ASTMUL LA COPIL

Astmul bronşic dezvoltat în copilărie are o prevalenţă crescută la nivel global. Printre factorii de risc este acceptată asocierea dintre existenţa unui teren atopic, expunerea la alergenii din mediu şi istoricul familial de boală alergică. Studii recente au sugerat că deficitul de vitamina D poate de asemenea predispune la fenotipul alergic. Vitamina D este un important modulator al sistemului imun şi reglator al proceselor de proliferare şi diferenţiere celulară. O serie de studii epidemiologice au arătat că deficitul de vitamina D este legat de creşterea incidenţei şi severităţii astmului la copii. În acest context, un grup de cercetători au desfăşurat un studiu în India având ca scop măsurarea nivelului seric al vitaminei D la copii astmatici şi compararea cu cel determinat la copii sănătoşi. Părinţii au fost chestionaţi despre: datele demografice, dieta copiilor şi aportul de vitamină D. La copii au fost determinate valorile serice pentru: vitamina D, calciu, fosfor, fosfatază alcalină, magneziu, creatinină şi hormon paratiroidian. Rezultatele au arătat că 68,1% dintre copiii astmatici au deficit de vitamina D, cu proporţii ale deficitului mediu şi sever semnificativ mai mari decât la copii sănătoşi. Istoricul familial pozitiv de deficit de vitamina D şi astm bronşic a fost semnificativ mai mare la copiii astmatici. Deficitul de vitamina D şi astmul au asociat, de asemenea, valori serice reduse ale fosforului şi magneziului, dar niveluri crescute ale fosfatazei alcaline serice şi IgE. Concentraţiile serice ale calciului, creatininei şi hormonului paratiroidian au fost similare la asmatici şi non-asmatici. Prin analiza statistică a rezultatelor cercetătorii au stabilit că deficienţa de vitamina D a fost cel mai puternic predictor al astmului la copil (OR 4.82; 95% CI 2.41-8.63, p <0,001) asociată cu prezenţa altor factori de risc: istoricul familial de astm şi de deficit de vitamina D şi concentraţii serice ridicate ale IgE. FOCUS ON QUALITY OF LIFE AND COSTS FOR IRON DEFICIT HEART FAILURE PATIENTS (Abstract): Chronic heart failure is an important health problem worldwide. Despite the reduction in mortality associated with the newest medical and interventional treatments, the quality of life remains an important concern for patients as well for doctors. **Aim:** to quantify the quality of life and the financial burden in patients with heart failure and iron deficiency. **Material and methods:** Patients with heart failure and iron deficiency were included in the study. Personal medical data were collected, and the patients completed the Kansas City Cardiomyopathy Questionnaire (KCCQ), which is a validated questionnaire for anemia associated with heart failure. The financial costs of hospital admission were evaluated. **Results:** A statistically significant moderate direct correlation between calcium channel blockers treatment and the scores in KCCQ was found. Also, a statistically significant, indirect correlation was shown between anticoagulant treatment and quality of life. As to the financial burden, the average cost per admission was 3,641.75 RON ± 1,881.32 RON (783.17 euro ± 404.58 euro). **Conclusions:** Anticoagulant treatment in patients with heart failure and iron deficiency was associated with reduced quality of life. Calcium channel blockers were associated with improvement of the quality of life in this category of patients. **Keywords:** HEART FAILURE, IRON DEFICIENCY, QUALITY OF LIFE, MEDICAL COSTS.

Chronic heart failure is associated with significant morbidity and in advanced stages has a higher mortality than many cancers (1). Current studies reveal an improvement in survival determined using evidence-based drugs and devices (2). Despite these results on mortality, many patients give equal or more importance to quality of life (QoL) when compared with length. QoL in patients with heart failure is importantly reduced compared with general population and with patients with other chronic diseases (3). Heart failure is responsible for enormous health costs and resource utilization. In United Kingdom this pathology accounts for 5% of emergency medical admissions to hospitals and is the primary diagnosis associated with hospital stay in German (4). Several studies support the importance of minimizing recurrent admissions as primary measure for reducing the economic burden of heart failure (5, 6). In this context, improvement of QoL and reduction of symptoms should be an im-

portant goal for clinicians.

Iron deficiency associated with heart failure leads to deterioration in QoL especially due to physical limitations in daily activities and a rise in hospital admission frequency (7). Iron deficiency is associated with impaired exercise capacity and fatigue in healthy populations (8). There is a growing interest to explore the determinants of QoL that could lead to interventions for improving of patient wellbeing.

In heart failure, patients receive treatment with the same classes of drugs for long periods of time. We understand the effects of this treatment on heart problems, but can this treatment influence differently the patients which associate iron deficiency? Could QoL be influenced by this treatment? We conducted a prospective study in patients with heart failure and iron deficiency to determine if the treatment used for heart failure could influence the QoL and its financial implications.

MATERIAL AND METHODS

An observational prospective study was conducted to evaluate different classes of drugs that could influence the QoL in patients with heart failure and iron deficiency.

Patients admitted to our Internal Medicine Clinic, diagnosed with heart failure (with reduced, mid-range and preserved ejection fraction) according to the diagnostic criteria of the latest European Society of Cardiology guidelines (9) and with associated iron deficiency (defined as serum iron <60 μg/dL with ferritin <100 μg/L or 100-300 μg/L with transferrin saturation <20%) were included in the study.

Detailed information on the drugs used before admission and past medical history were recorded for each patient.

Patients with positive fecal occult test or with pre-existing or newly diagnosed conditions that could lead to anemia were excluded. The patients with chronic blood loss (recurrent epistaxis, hematuria, menometrorrhagia, gastrointestinal bleeding), neoplasia, inflammatory disease, pregnancy, recent surgery, anemia that required blood transfusion were excluded from our analysis.

Blood samples for laboratory tests were collected early in the morning after overnight fast. After inclusion, each patient completed the Kansas City Cardiomyopathy Questionnaire (KCCQ). This is a 23-item self-administered questionnaire and is a disease-specific measure that quantifies some clinically relevant domains of patient health: physical limitation, symptoms (frequency, severity, changes over time), quality of life assessment in heart failure, social function, self-efficacy and knowledge. All these scales can be combined into a single, overall summary score. Scores range from 0 to 100, higher scores indicating fewer symptoms and better QoL. This is a validated instrument to evaluate the QoL in patients with heart failure and anemia (10).

Finally, as a major public health issue, the financial costs of hospital admissions were of interest. Variables like the length of hospital stay and in hospital costs were analyzed in a subgroup of 20 patients. All costs are in RON (the currency of Romania) and were converted to euros (2018 exchange rate using the National Bank of Romania inflation calculator).

The study design was approved by the Research Ethics Committee of the Iasi "Grigore T. Popa" University of Medicine and Pharmacy and by the Ethics Committee of the "Sf. Spiridon" County Clinical Emergency Hospital. All participants were informed about the study protocol and signed the informed consent.

Data are presented as mean ± standard deviation (SD) or as percentages.

Point biserial correlation was used to investigate the relations between certain nominal variables.

Means between groups were compared using Mann Whitney U test for two samples. The statistical software used was *IBM Statistics SPSS 20* for Windows. All tests were two-tailed and a p-value <0.05 was considered statistically significant.

RESULTS

Included in the study were 125 patients who met the inclusion criteria and completed the KCCQ. Of these 54,68 % were female, 45,31% male and the mean age was 73.18 (range 42-98) years. Based on the type of heart failure, 21.87% were categorized as reduced ejection fraction, 22.65% as mid-range ejection fraction and 38.28% as preserved ejection fraction. According to New York Heart Association (NYHA) classification, 45.6% were in NYHA class II, 52% in NYHA class III and only 2.4% of the patients were NYHA class IV. The main characteristics of patients are presented in table I.

TABLE I

Descriptive statistics of the patients included in the study

Parameter	Mean	SD	95% Confidence Interval	
			Lower Bound	Upper Bound
Hemoglobin (g/dL)	12.37	1.62	11.94	12.96
Hematocrit (%)	38.65	6.07	37.58	39.72
MCV (fl)	86.11	8.78	84.57	87.65
MCH (pg)	27.7	2.58	27.25	28.16
MCHC (g/dL)	31.95	1.31	31.72	32.18
Iron (µg/dL)	38.33	12.05	32.37	39.84
Ferritin (ng/mL)	86.51	97.21	69.37	103.65
NT-proBNP (pg/mL)	4730.72	6681.87	3391.09	6070.35
Urea (mg/dL)	48.92	18.78	45.58	52.26
Creatinine (mg/dL)	0.99	0.34	0.93	1.05
eGFR (mL/min/1.73m²)	71.28	22.43	67.34	75.22
C-reactive protein(mg/dL)	2.41	5.48	1.38	3.45
LVEF (%)	49.79	13.47	44.34	48.82

MCV-mean corpuscular volume; MCH-mean corpuscular hemoglobin; MCHC-mean corpuscular hemoglobin concentration; NT-proBNP - N terminal pro brain natriuretic peptide; eGFR-estimated glomerular filtration rate; LVEF-left ventricular ejection fraction; SD-standard deviation

The patients were divided into groups according to the treatment followed before admission. The percentage of patients using different drugs is shown in fig. 1.

To investigate the correlations between different classes of drugs and QoL, point biserial correlation was used. A significant moderate direct correlation between calcium channel blocker (CBB) treatment and the scores on KCCQ related to symptoms was found (tab II).

A statistically significant, indirect correlation was found between anticoagulant treatment and QoL (r -0.2, p 0.02), social limitation (r -0.28, p 0.001) and combined

scores (r -0.23, p 0.01; r -0.17, p 0.05).

No other significant correlations were found between beta blockers, angiotensin converting enzyme inhibitors (ACEI) or antiplatelet treatment and the KCCQ scores.

In the subgroup of patients evaluated for in-hospital costs, the average hospital stay was 8.75 ± 4.54 days and the average cost per admission was 3641.75 RON ± 1881.32 RON (783.17 euro ± 404.58 euro). All financial data were certified by the Hospital Financial Department and were collected at discharge according to the national economic regulations.

DISCUSSION

This study shows that the treatment used for heart failure has an influence on QoL of patients. It appears that symptoms and social limitation were improved in patients receiving CCB. One of the explanations for this result is the fact that most of the patients included in this analysis (38%) had heart failure with preserved ejection fraction.

CCB do not have a specific indication in heart failure, so there are no studies aimed at evaluating QoL in this category of patients. A research, involving hypertensive patients, showed that patients treated with CCBs have a better QoL (11).

It was proved that iron deficiency has a negative impact on QoL independent of the presence of anemia (12). This effect is determined mostly by physical limitation in daily activities, secondary to cardiac and skeletal muscle dysfunction (13). It is possible that CCBs determine vasodilation which exceeds the negative effect of iron deficiency. However, these hypotheses need to be proven in large randomized studies.

According to our results, anticoagulant treatment has a negative effect on QoL in patients with heart failure and iron deficiency. The correlation was moderate statistically significant. Patients with an indication for anticoagulant treatment were expected to be in a more advanced stage of heart failure, and, therefore, their QoL was reduced. Furthermore, patients with anticoagulant treatment could have intermittent digestive blood loss and, therefore, a higher degree of iron deficiency that could explain these results.

It has already been shown that anticoagulant treatment determines a reduction in QoL especially at the beginning of treatment. Qol is more influenced by other drugs that could increase the anticoagulant effect (14).

However, the anticoagulant therapy is indicated for the prevention of embolic events, so this advantage exceeds the impact of QoL.

We could not find an improvement on QoL in patients receiving beta blockers or ACEI treatment, but this result is in accordance with other larger studies (15,16).

The unpredictable clinical course of heart failure has a significant socioeconomic impact. A compensated heart failure results in improvement in QoL and large cost savings. Our study emphasizes the necessity of assessing the financial aspects of patients with heart failure admitted to Romanian public hospitals. Further efforts are needed to establish proper measures of prevention of cardiac disease and reducing hospital readmissions.

There are some limitations of the present study. First, the number of patients included in the analysis is limited but, considering the inclusion and exclusion criteria, we believe that it is eloquent for the investigated disease. In addition, we excluded patients who could have another cause of iron deficiency except heart failure, this way limiting possible biases. The questionnaire being self-administered, the responses could be influenced by the social status of the patients.

CONCLUSIONS

Our study revealed that the group of patients associating iron deficiency could benefit from CCB treatment. Anticoagulants can reduce QoL. These results are important for personalizing the treatment

for heart failure according to the presence of other comorbidities (i.e. iron deficiency) with respect to optimal QoL and balanced financial costs.

NEWLY DIAGNOSED PERIPHERAL ARTERIAL DISEASE IN PATIENTS WITH CARDIOVASCULAR RISK FACTOR (Abstract): The gold of this study is to investigate the utility of ankle-brachial index (cut-off value < 0,90) as an indicator of peripheral arterial disease in a group of patients hospitalized in the Medical Clinic and to assess the prevalence of risk factor and associated comorbidities in patients with low index. **Material and methods:** A total of 202 patients older than 50 years with established cardiovascular or cerebrovascular disease or at least one cardiovascular risk factor (smoking, diabetes, dyslipidemia and hypertension) underwent ankle-brachial index measurement for this study. Demographic data and cardiovascular risk factor were analyzed. We assessed medical history, symptoms and clinical examination. **Results;** In this study, a number of 72 patients (35.64%) were diagnosed with peripheral arterial disease. Our results indicated that advanced age, greater number of total risk factors and presence of peripheral arterial disease related physical findings were associated with increased likelihood of low ankle-brachial index. **Conclusions.** We should recommend ankle-brachial index as screening test in pacients older than 50 years, in the presence of at least one cardiovascular risk factor, for early detection of peripheral arterial disease and systemic atherosclerosis, to improve prevention and early aggressive treatment. **Key words:** PERIPHERAL ARTERIAL DISEASE, ANKLE-BRACHIAL INDEX, RISK FACTOR, EPIDEMIOLOGY

Boala arterială periferică (BAP) constituie un capitol important în patologia cardiovasculară, datorită incidenţei ridicate şi problemelor complexe de diagnostic şi tratament pe care le ridică. BAP este un marker al aterosclerozei, care asociază frecvent determinări vasculare şi în alte teritorii: cardiovascular, cerebrovascular sau renal.

Studiile epidemiologice au estimat că prevalenţa BAP poate fi de până la 10% în populaţia generală şi de două ori mai mare la cei cu vârsta peste 70 de ani. Mai mult, la fiecare pacient diagnosticat cu BAP simptomatică, există aproximativ 3 la 4 pacienţi nediagnosticaţi, cu BAP asimptomatică.

Pacientul cu BAP are un risc de deces în următorii 10 ani de 6 ori mai mare decât populaţia generală, un risc de infarct miocardic fatal de 4 ori mai mare şi un risc de accident vascular cerebral, inclusiv atac ischemic tranzitor, de 2 - 3 ori mai mare.

Excluzând pacienţii cu ischemie critică a membrelor inferioare, pacienţii cu BAP au o incidenţă anuală de 2 - 3% a unui infarct miocardic non-fatal şi un risc de 2 –

3 ori mai mare decât populaţia generală de a dezvolta angină pectorală. Morbiditatea şi mortalitatea la 5, respectiv 10 şi 15 ani sunt de aproximativ 30%, respectiv 50% şi 70%, la aceşti pacienţi.

Valorile incidenţei şi prevalenţei arteriopatiei obliterante sunt dificil de stabilit întrucât această afecţiune cuprinde şi un stadiu asimptomatic. Aceasta poate fi descoperită cu ocazia unei evaluări generale a unui pacient asimptomatic sau a unuia cunoscut cu afectare aterosclerotică manifestă într-un alt teritoriu arterial (1, 2, 3).

Scopul acestui studiu este de a investiga utilitatea indicelui gleznă-braţ (IGB<0,90) ca indicator al BAP la o populaţie internată în Clinica Medicală şi de a evalua caracteristicile indivizilor cu IGB scăzut în raport cu sexul, vârsta şi prezenţa unei boli cardiovasculare sau cerebrovasculare cunoscute sau a unor factori de risc cardiovascular.

MATERIAL ŞI METODE

Au fost incluşi în studiu 202 pacienţi internaţi, în perioada februarie – mai 2011, în Clinica I Medicală Cardiologică, cu vârste cuprinse între 50 – 89 ani, care nu au fost diagnosticaţi anterior cu BAP, în prezenţa unei boli cardiovasculare sau cerebrovasculare cunoscute sau a cel puţin un factor de risc cardiovascular major (fumat, diabet, HTA, dislipidemie).

Au fost considerate criterii de excludere BAP cunoscută, refuzul pacientului şi condiţiile ce necesită spitalizare pentru afecţiuni ameninţătoare de viaţă sau neoplasme.

Au fost urmărite şi corelate datele demografice, comorbidităţile asociate, prezenţa factorilor de risc cardiovascular, examenul clinic sugestiv pentru BAP (absenţa pulsului la artera pedioasă sau tibială posterioară, prezenţa unui suflu arterial sau a unor tulburări trofice cutanate) şi simptomatologia clinică (asimptomatici, simptomatici – cu claudicaţie intermitentă şi simptomatici sever – cu durere de repaus şi/sau tulburări trofice cutanate prezente, interpretate în contextul comorbidităţilor – insuficienţă venoasă cronică, polineuropatie diabetică) (fig.1).

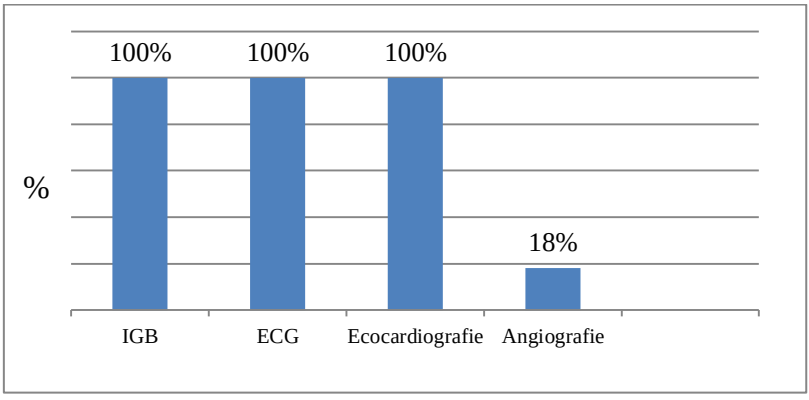

Fig. 1. Protocolul de urmărire – Indicele gleznă-braţ (IGB), electrocardiograma (ECG), ecocardiografia şi explorarea angiografică a arterelor membrului inferior.

Protocolul de urmărire a lotului de studiu a cuprins IGB, electrocardiogramă şi ecografie cardiacă efectuată întregului lot de 202 (100%) pacienţi şi explorarea arterială a membrelor inferioare la 36 (17,82%). La acestea s-au adăugat testarea

glicemiei, funcţiei renale (uree, creatinină, clearance de creatinină, acid uric), profilului lipidic (colesterol total, HDL-colesterol, LDL-colesterol, trigliceride), fibrinogenului şi hematocritului.

IGB este un indicator uşor de obţinut şi care se realizează cu costuri minime. El reprezintă raportul dintre tensiunea arterială sistolică (TAS) de la nivelul gleznei şi tensiunea la nivelul arterei brahiale. O valoare IGB<0,90 are o sensibilitate de 95% şi o specificitate de 99% pentru diagnosticul arteriopatiei obliterante a membrelor inferioare. Este metoda validată pentru screening la toate categoriile de pacienţi şi pentru diagnosticul iniţial al BAP, care depistează BAP semnificativă hemodinamic la pacienţi asimptomatici (2, 3).

Măsurarea IGB s-a realizat prin măsurarea TAS cu ajutorul unui tensiometru standard la ambele arterele brahiale şi la ambele artere pedioase şi tibiale posterioare după repaus de cel puţin 5 minute în decubit dorsal. La membrele superioare, TAS s-a măsurat în mod convenţional. TAS la membrele inferioare s-a evaluat prin plasarea unei manşete pe gleznă şi gonflarea sa peste valoarea TAS de la braţ, cu înregistrarea succesiv a primului semnal Doppler audibil la nivelul arterei pedioase şi tibiale posterioare cu ajutorul unei sonde speciale de 10 mHz. Pentru calculul IGB, s-a utilizat întotdeauna valoarea cea mai mare a TAS brahiale măsurate la nivelul membrului superior drept sau stâng, iar la membrul inferior valoarea cea mai mare dintre TAS la pedioasă şi tibiala posterioară (2).

Analiza statistică a fost realizată cu ajutorul programelor *SPSS 13.0* şi *Statistica 6.0* după prealabila introducere a datelor în Microsoft Excel. Pentru compararea valorilor medii am utilizat testul t Student şi ANOVA . Analiza corelaţiilor s-a efectuat cu ajutorul coeficientului de corelaţie Pearson. Datele au fost exprimate în valoare medie±deviaţie standard sau în procente. Semnificaţia statistică a fost luată în considerare pentru un nivel de $p<0,05$.

REZULTATE ŞI DISCUŢII

Cercetările noastre au fost motivate de apariţia studiului CAREFUL, singurul publicat anterior care a urmărit prezenţa BAP pe un lot de 530 pacienţi cu boală cardiovasculară sau cerebrovasculară cunoscută sau în prezenţa a cel puţin un factor de risc cardiovascular prezent, prin măsurarea IGB (4).

Lotul de studiu a cuprins 104 (51,49%) bărbaţi şi 98 (48,51%) femei, cu o medie de vârstă a lotului de 70,67±9,21 ani, fără diferenţe semnificative între cele 2 sexe, cu domiciliul preponderent în mediul rural 126 (62,38%) pacienţi.

Distribuţia pe grupuri de vârstă a evidenţiat că: între 50-59 ani au fost 32 (15,84%) pacienţi; 60-69 – 38 (18,81%); 70-79 – 102 (50,5%), iar între 80-89 – 30 (14,85%) pacienţi (fig. 2).

Au fost evaluate evenimentele aterotrombotice în cadrul lotului: antecedentele personale patologice (APP) cardiovasculare au fost prezente la 194 (96,04%) pacienţi, cerebrovasculare - 26 (12,87%), iar renale - 12 (5,94%) cazuri.

Evenimentele cardiovasculare au fost dominate de HTA pentru 70,51% cazuri (66 bărbaţi, 76 femei), urmată de fibrilaţia atrială la 35,62% (38 bărbaţi, 34 femei), iar cele cerebrovasculare de accident vascular cerebral în 7,81% cazuri (12 bărbaţi, 4 femei).

APP cardiovasculare au fost prezente în proporţii asemănătoare la cele 2 sexe (94,23% la sexul masculin versus 97,96% la feminin), în timp ce istoricul de boală cerebrovasculară a fost semnalat în propor-

ție mai mare în rândul bărbaților (19,23% la masculin versus 6,12% la feminin).

Au fost evaluați factorii de risc cardiovascular prezenți: dislipidemia a fost cel mai frecvent factor de risc prezent (58,42%), urmată de obezitate şi diabet, în proporții apropiate (39,6%, respectiv 37,62%), iar fumatul a fost implicat în 26,73% cazuri, îndeosebi bărbați care au fost mai frecvent diagnosticați cu diabet şi obezitate.

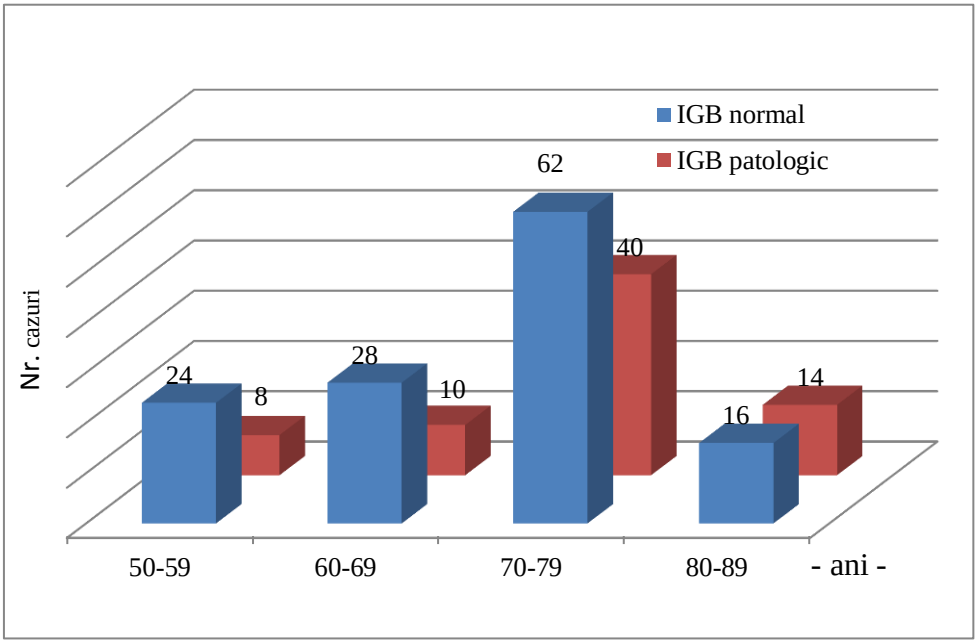

Fig. 2. Prezența bolii arteriale periferice repartizată pe grupuri de vârstă.

Din totalul pacienților incluşi în studiu, 52 (25,74%) au avut un singur factor de risc prezent; 68 (33,66%) – 2; 40 (19,8%) – 3; 18 (3,96%) – 4, iar 52 (25,74%) pacienți nu au avut nici un factor de risc prezent, dar au avut patologie cardiacă sau cerebrovasculară asociată.

În cadrul lotului studiat, BAP a fost descoperită la 72 (35,64%) pacienți prin determinarea IGB, considerând ca diagnostică o valoare IGB<0,90. Boala a fost mai frecvent evidențiată la sexul masculin (44 bărbați versus 28 femei, $p<0,05$) şi în decada de vârstă 70-79 de ani (55,6%), dar avem în vedere că aproape jumătate din lot se încadrează în această vârstă. BAP a fost diagnosticată într-o proporție de 19,4% în decada de vârstă 80-89 de ani şi a fost mai puțin frecventă în decadele 60-69, respectiv 50-59 ani (13,9%, respectiv 11,1%).

Studiul CAREFUL, realizat pe un lot de 530 pacienți cu aceleaşi criterii de includere ca şi studiul nostru, a evidențiat prezența BAP în 25,1% din cazuri, cu o prevalență mai mare, de 30% la vârstnicii peste 70 de ani, indiferent de factorii de risc cardiovascular asociati (4).

Incidența semnificativ crescută a BAP în cadrul lotului studiat comparativ cu datele din literatură este explicată, pe de o parte, de faptul că în România adresabilitatea

pacientului arteriopat la medic este tardivă, în stadii simptomatice de boală, dar şi de faptul că am inclus în studiu 22 de pacienţi cu tulburări trofice cutanate la nivelul membrelor inferioare de etiologie neprecizată în momentul internării, care s-au dovedit ulterior a fi de cauză vasculară, asociate sau nu cu neuropatie periferică.

Din totalul pacienţilor nou diagnosticaţi cu BAP, 18 (8,91%) au prezentat BAP simptomatică, acuzând claudicaţie intermitentă; 36 (17,82%) cu BAP simptomatică sever, prezentând durere de repaus şi/sau tulburări trofice cutanate şi 18 (8,91%) cu BAP asimptomatică, neavând simptome sugestive pentru BAP (fig.3).

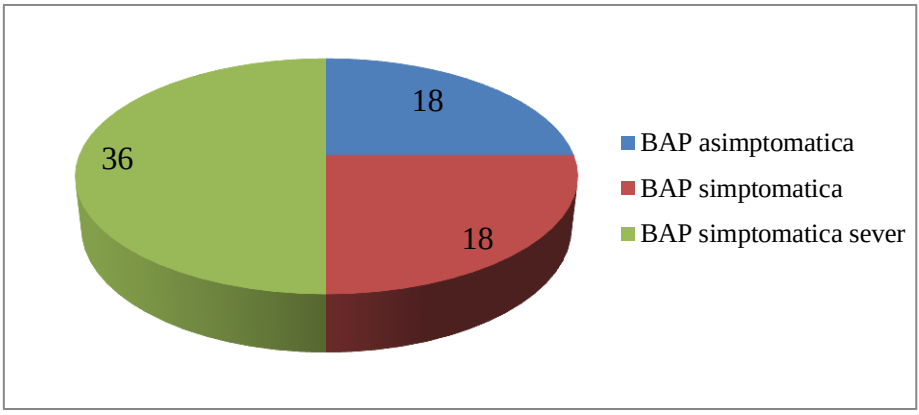

Fig. 3. Stadiul clinic al bolii arteriale periferice în relaţie cu examenul clinic şi simptomatologia pacientului.

Studiul PARTNERS realizat pe 6979 de pacienţi cu vârste peste 50 de ani sau în prezenţa unui factor de risc (fumat sau diabet) a urmărit capacitatea de depistare a BAP folosind IGB. Rezultatele arată un procent semnificativ de BAP de 29% (1865 pacienţi), dintre care 825 cu BAP izolată şi 1040 cu BAP asociată cu boală cardiovasculară. De remarcat, în studiul PARTNERS, că doar 8,7% din totalul pacienţilor identificaţi cu BAP au prezentat istoric de claudicaţie tipică (5).

În studiul actual, BAP simptomatică, cu istoric de claudicaţie intermitentă, a fost depistată în 8,91% cazuri, valoare similară cu studiile anterioare, care raportează valori între 5,3% - 18,9% pentru BAP simptomatică (6, 7, 8).

Din totalul pacienţilor luaţi în studiu, un număr de 10 (4,95%) au avut cel puţin o valoare IGB>1,3, valoare considerată fals supraunitară, apărute la pacienţi vârstnici şi diabetici, probabil datorate calcificării arteriale, dar care nu au fost incluşi în categoria BAP nou diagnosticată, procent uşor mai scăzut decât în studiile anterioare (5).

Din totalul pacienţilor diagnosticaţi cu BAP, 26 (33%) au prezentat BAP unilaterală, iar 48 (67%) bilaterală.

În studiul nostru, BAP a fost confirmată prin efectuarea IGB la toţi pacienţii care au prezentat suflu la ascultaţia arterelor femurale (6 pacienţi) şi tulburări trofice cutanate (22; eritem – 14; ulceraţii – 6; necroză – 4). S-a obţinut, de asemenea, confirmarea diagnosticului la peste 90% (58) din pacienţii care la examenul clinic au prezentat puls periferic absent la nivelul arterei pedioase

sau tibiale posterioare. Au fost doar 6 pacienți care au avut puls periferic absent, dar IGB>0,9 a infirmat diagnosticul de BAP, pacienții prezentând obezitate, edeme ale membrelor inferioare datorate insuficienței cardiace sau insuficienței venoase cronice.

Pentru diagnosticul de BAP sunt foarte importante anamneza dirijată cu descrierea claudicației intermitente sau a durerii de repaus şi examenul clinic al pacientului sugestiv pentru BAP, cu examenul arterelor membrelor inferioare şi depistarea leziunilor trofice cutanate, cu confirmarea ulterioară prin efectuarea IGB şi eventual explorare arteriografică, pentru stabilirea unei conduite terapeutice optime. Studiul actual confirmă, ca şi cele anterioare, importanța examenului clinic al pacientului, cu limitele induse de prezența comorbidităților asociate (5, 7, 9, 10, 11).

S-a efectuat arteriografie la 36 de pacienți cu IGB<0,9, reprezentând un procent de 50% din totalul pacienților diagnosticați cu BAP, aflați în stadiile Leriche IIB, III şi IV de boală. Confirmarea angiografică a BAP a fost obținută la toți cei 36 de pacienți explorați, dintre care 14 au prezentat leziune tip stenoză arterială, iar 28 tromboză arterială, cele mai multe localizări fiind la nivelul arterei femurale superficiale (32 pacienți).

CONCLUZII

Studiul arată o incidență crescută a BAP nou diagnosticate în rândul pacienților internați în Clinica Medicală, care au un eveniment aterotrombotic în antecedente sau cel puțin un factor de risc cardiovascular prezent. Rezultatele arată că vârsta înaintată, prezența unui număr mai mare de factori de risc şi constatarea unor semne clinice sugestive pentru BAP au fost asociate cu un IGB scăzut.

S-a evidențiat utilitatea în sistem screening a IGB la pacienții cu vârsta peste 50 de ani, în prezența a cel puțin unui factor de risc cardiovascular, pentru depistarea precoce a BAP şi a aterosclerozei sistemice, pentru îmbunătățirea prevenției şi un tratament agresiv precoce.

NOUTĂŢI

RISCUL APARITIEI CANCERULUI LA PACIENTII CARE PRIMESC TRATAMENT CU STATINE

Statinele sunt prescrise pe scară largă în tratamentul dislipidemiei, aterosclerozei, şi pentru reducerea riscurilor cardiovasculare. Date ştiinţifice contradictorii au generat o dezbatere cu privire la asocierea utilizării statinelor cu riscul aparitiei cancerului. Unele studii au demonstrat că terapia cu statine este bine tolerată şi sigură, inclusiv în utilizarea pe termen lung, alte studii au contrazis această concluzie. Dar, toate aceste studii au avut o serie de limitări legate de numărul şi caracteristicile subiecţilor studiaţi, perioada scurtă de monitorizare, constrângerile de selecţie a pacienţilor şi rigiditatea protocoalelor de tratament tipice studiilor randomizate, controlate. Pentru a corecta aceste limitări, un grup de cercetători americani a efectuat un studiu de cohortă retrospectivă a incidenţei cancerului la persoanele în vârstă care au folosit şi care nu au folosit statine. Mai mult de 11 milioane de înregistrări medicale, din perioada ianuarie 1990- februarie 2009 au fost extrase din baza de date a General Electric Centricity. Prin metode statistice au fost selectate 45857 de perechi de pacienţi cu caracteristici similare pentru utilizarea statinelor. Studiul a demonstrat că incidenţa cancerului la pacienţii care au primit tratament cu statine a fost 11.37%, comparativ cu 11,11% la pacienţii care nu au primit acest tratament. Analiza Cox de regresie a arătat o rată a riscului nesemnificativă de 1,04 (interval de încredere 95%: 0.99 - 1.09). Curbele Kaplan-Meier pentru diagnosticul de cancer până la 10 ani nu au arătat diferenţe între cele doua loturi de pacienti. Concluziile acestei analize retrospective au fost că nu există risc semnificativ statistic crescut de cancer asociat cu statine (Claudio Marelli, Candace Gunnarsson, Susan Ross et al. Statins and risk of cancer, a retrospective cohort analysis of 45,857 matched pairs from an electronic medical records database of 11 million adult Americans. *J Am Coll Cardiol*. 2011; 58(5): 530-537).

MONITORING OF MYCOBACTERIUM TUBERCULOSIS INFECTIONS IN IASI COUNTY IN 2009 (Abstract): Tuberculosis is a major public health problem worldwide. Our study aimed to investigate epidemiological and demographic characteristics of tuberculosis infection and resistance to antituberculous drugs in Iasi County in 2009. **Material and method**: We have analysed the epidemiological parameters for 687 patients with pulmonary tuberculosis, new cases confirmed by microscopy and cultivation on Lowenstein Jensen. First and second-line antituberculous susceptibility testing was done for 130 strains, using agar proportion method and absolute-concentration method. **Results**: The number of new cases of tuberculosis was higher in rural areas and in males 41-50 years old (sex ratio=2.22). The proportion of positive cases in microscopy was 81.51%. Drug resistance was as follows: 16 isolates (12.3%) to isoniazid, 5 (3.84%) to rifampin, 2 (1.53%) to ethambutol, 2 (1.53%) to streptomycin and 4 (3.07%) were multidrug-resistant. **Conclusions**: In this study we found high resistance rates to isoniazid, streptomycin and ethambutol. This requires increasing efficiency of tuberculosis diagnosis and susceptibility testing. **Key words**: TUBERCULOSIS, DRUG RESISTANCE, MYCOBACTERIUM TUBERCULOSIS

Tuberculoza (TB) este una dintre problemele majore de sănătate publică pe plan mondial, Organizaţia Mondială a Sănătăţii (OMS) estimând că 32% din populaţia globului este infectată cu *Mycobacterium tuberculosis* (1). În ţările Uniunii Europene, în anul 2008, s-a raportat un număr de 315.285 cazuri noi de tuberculoză şi 45.448 decese prin tuberculoză, iar în România, în anul 2009 au fost diagnosticate 14.648 de cazuri noi de tuberculoză pulmonară dintr-un total de 21.457 cazuri înregistrate (2). Aceasta reprezintă o importantă problemă de sănătate publică nu doar datorită incidenţei crescute ci şi datorită dificultăţilor terapeutice şi a asocierii factorilor socio-economici dificil de controlat dar care constituie parte integrantă a managementului acestor cazuri.

Referitor la dificultăţile terapeutice, literatura de specialitate menţionează că tuberculoza multi-drog rezistentă (MDR TB),

definită prin rezistenţa cel puţin la izoniazidă (HIN) şi rifampicină (RMP) a atins în 2008 o proporţie de 6% din totalul cazurilor înregistrate în 25 de ţări europene, iar România a înregistrat cel mai mare procent MDR TB (14,7%), după cele raportate de Ţările Baltice (1,3). De asemenea, rezistenţa extensivă – XDR (rezistenţa la HIN, RMP, fluorochinolone şi cel puţin unul dintre următoarele droguri injectabile: amikacina, capreomicina sau kanamicina) îmbracă de asemenea proporţii îngrijorătoare la nivel european: 7,3% în 2008, când România a raportat 54 de cazuri (1).

OBIECTIVE

Acest studiu retrospectiv şi-a propus descrierea caracteristicilor epidemiologice şi demografice ale infecţiei tuberculoase în judeţul Iaşi şi pe cele legate de rezistenţa la antituberculoase. În acelaşi timp, acest studiu constituie o motivaţie pentru optimizarea metodelor de diagnostic în ceea ce priveşte raportul timp/beneficiu şi a mijloacelor de monitorizare a rezistenţei la antituberculoase, prin metode de înaltă sensibilitate şi specificitate.

MATERIAL ŞI METODĂ

Lotul de studiu a cuprins un număr de 687 de pacienţi cu tuberculoză pulmonară, cazuri noi, confirmate bacteriologic în perioada ianuarie-decembrie 2009 în cadrul Laboratorului Spitalului Clinic de Pneumoftiziologie Iaşi. Cazul nou este definit ca pacient care nu a primit niciodată tratament cu medicamente antituberculoase în asociere pe o perioadă mai mare de o lună de zile.

A fost urmărită repartiţia cazurilor pe vârstă, sex, mediu de provenienţă, sensibilitate la antituberculoase de prima şi a doua linie.

Diagnosticul de laborator a fost efectuat pe baza examenului microscopic al frotiurilor din probe clinice colorate Ziehl-Neelsen, urmat de izolarea, identificarea culturii bacteriene şi testarea sensibilităţii la antibiotice.

Izolarea tulpinilor de *Mycobacterium tuberculosis* a fost efectuată prin însămânţarea pe mediul Löwenstein-Jensen a probelor ca atare sau decontaminate chimic în funcţie de condiţia lor microbiologică. Identificarea de specie s-a bazat pe: caracterele microscopice în coloraţie Ziehl-Neelsen (acido-alcoolo-rezistenţa, dispoziţia în corzi), caracterele de cultură (viteza de creştere pe subcultură, aspectul coloniilor, pigmentogeneza), caracterele biochimice (producerea de catalază, producerea de niacină, nitrat reductază) (4).

Pentru un număr de 130 de tulpini izolate de la pacienţi nou diagnosticaţi a fost făcută testarea sensibilităţii la antituberculoase de prima linie (izoniazida, rifampicina, pirazinamida, etambutolul, streptomicina) şi a doua linie (etionamida, ofloxacina, kanamicina, capreomicina, acidul paraaminosalicilic, cicloserina), prin metoda proporţiilor (Canetti) şi metoda concentraţiilor absolute (Meissner) aşa cum stabileşte Programul Naţional de Control al Tuberculozei. Metodele de testare utilizate compară creşterea bacteriană de pe tuburile test (conţinând medicamente), cu cea de pe tuburile martor, după însămânţarea unui eşantion reprezentativ din populaţia bacilară de testat (4). Rezistenţa este definită prin prezenţa unei proporţii de mutanţi rezistenţi mai mare de 1% din populaţia martor.

REZULTATE

Dintre cei 687 de pacienţi, 474 (68,99%) au fost bărbaţi, iar în funcţie de mediul de provenienţă, am constat că 418 (60,84%) proveneau din mediul rural.

În ceea ce priveşte repartiţia cazurilor pe grupe de vârstă, grupa 41-50 de ani a fost cea mai afectată (198 de cazuri, 28,82%) şi s-a constatat un număr de 12 cazuri (1,74%) la copii (fig. 1).

Examenul microscopic a evidenţiat un număr de 560 de cazuri noi microscopic pozitive, reprezentând 81,51% din totalul de 687 de cazuri noi de TB înregistrate.

Rata de depistare a cazurilor noi pulmonare, microscopic pozitive a atins o valoare de 14,06% din 3982 cazuri suspecte examinate bacteriologic.

Dintre cele 687 cazuri noi pozitive în cultură, 127 au fost microscopic negative reprezentând o proporţie de 18,48%.

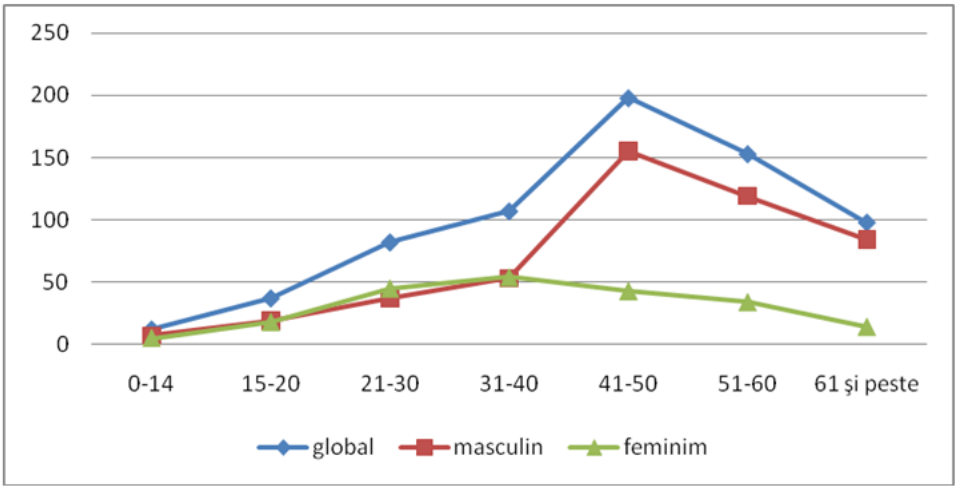

Fig. 1. Repartiţia cazurilor pe vârstă şi sex

În ceea ce priveşte sensibilitatea la antituberculoase, am testat 18,92% din totalul pacienţilor investigaţi, iar din cele 130 de tulpini testate, 25 de tulpini au fost monorezistente (19,23%), 16 tulpini au prezentat polirezistenţă (12,3%), iar 4 tulpini au fost MDR (3,07%).

Monorezistenţa la HIN a fost identificată la 16 tulpini (12,3%), pentru RMP la 5 tulpini (3,84%) iar pentru streptomicină (SM) şi respectiv etambutol (EMB) la 1,53% din cazuri (2 tulpini).

Polirezistenţa (definită ca rezistenţa la 2 antituberculoase cu excluderea asocierii HIN- RMP) a fost repartizată astfel: 15 tulpini au avut polirezistenţă la HIN şi SM (11,53%) iar o tulpină a prezentat polirezistenţă la HIN şi EMB (0,75%) (tab. I).

TABELUL I

Repartiţia tulpinilor funcţie de rezistenţă la antituberculoase de linia întâi

Rezistenţă	Nr. cazuri	Rata%
Monorezistenţă	25	19,23
HIN	16	12,3
RMP	5	3,84
SM	2	1,53
EMB	2	1,53
Polirezistenţă	16	12,3
HIN-SM	15	11,53
HIN-EMB	1	0,75
MDR	4	3,07

DISCUŢII

În 2009, în România a fost înregistrată o rată a incidenţei tuberculozei de 125 cazuri la 100.000 de locuitori, cifră care situează ţara noastră pe primul loc în Uniunea Europeană.

În ceea ce priveşte caracteristicile lotului remarcăm preponderenţa sexului masculin (68,99%), cu diferenţe statistic semnificative, majoritatea pacienţilor provenind din mediul rural (60.84%).

Rezultatele obţinute sunt concordante cu cele din literatură. În ceea ce priveşte repartiţia pe sexe, rezultatele obţinute arată că frecvenţa tuberculozei la bărbaţi este de 2,22 ori mai mare decât la femei, proporţie comparabilă cu cea menţionată în raportările OMS (sex ratio = 2,3) (3).

Procentul mai mare de cazuri noi de TB înregistrate în mediul rural comparativ cu mediul urban este justificat prin nivelul scăzut al condiţiilor socio-economice, educaţia sanitară deficitară şi accesul mai dificil la asistenţă medicală, în special în zonele defavorizate economic aşa cum este regiunea geografică de care aparţine judeţul Iaşi.

De asemenea, repartiţia pe grupe de vârste a arătat diferenţe între cele două sexe: cele mai multe îmbolnăviri apar la bărbaţi în jurul vârstei de 50 de ani, iar la femei la vârste mai tinere, în jur de 30 de ani. Această observaţie sugerează că transmiterea infecţiei în populaţie nu este pe deplin controlată (5).

Referitor la diagnosticul bacteriologic, proporţia cazurilor noi pozitive prin microscopie, raportată la toate cazurile noi pulmonare este peste 60%, ceea ce demonstrează că sunt respectate standardele de calitate în efectuarea acestuia (5). Rezultatele noastre nu au inclus cazurile noi de TB diagnosticate prin criterii clinice şi radiologice şi neconfirmate bacteriologic deoarece managementul acestor cazuri este independent de confirmarea bacteriologică.

Din analiza statistică a datelor remarcăm o importantă creştere a rezistenţei la antibiotice, concordantă cu evoluţia ratelor la nivel mondial. În evaluările OMS, România a raportat pentru cazurile noi de TB în 2008 o rată de rezistenţă la HIN de 8,7%, la RMP 4,9%, la SM 0,7% iar la EMB 1,2%. Procentul cazurilor noi de TB MDR a avut o evoluţie ascendentă de la 2,8% în 2005 la 4,3% în 2008 (3). Remarcăm că în studiul nostru ratele de rezistenţă au valori superioare celor din literatură, cu excepţia celor pentru RMP şi MDR. Acest aspect se corelează cu lipsa complianţei pacienţilor la schema terapeutică datorată atât aspectelor socio-economice (accesul scăzut la îngrijiri de sănătate, educaţie sanitară precară, lipsa suportului familial), cât şi a celor legate de durata mare a tratamentului şi a multiplelor reacţii adverse.

Cunoaşterea acestor date este importantă, deoarece monorezistenţa prelungeşte durata tratamentului antituberculos până la 12 luni în cazul rezistenţei la HIN şi până la 18 luni în cazul rezistenţei la RMP. Monorezistenţa la HIN sau SM este calea de achiziţie a rezistenţelor adiţionale. Rezistenţa la RMP este considerată predictivă pentru TB MDR. Costul mediu al unui tratament individualizat pentru MDR TB este de aproape zece ori mai mare comparativ cu tratamentul tuberculozei chimiosensibile, fiind estimat la 9.000 - 20.000 RON, în funcţie de schema terapeutică şi de durată.

CONCLUZII

Cu toate că la nivel mondial se desfăşoară, prin intermediul OMS, programe de supraveghere şi control al tuberculozei, rata incidenţei globale a infecţiei rămâne cres-

cută (137 de cazuri la 100.000 de locuitori, 2009), ceea ce impune intensificarea eforturilor de depistare a cazurilor noi şi de optimizare a metodelor de diagnostic, tratament şi supraveghere. Creşterea ratei depistării cazurilor noi se poate realiza prin introducerea de noi metode de diagnostic, cu sensibilitate comparabilă, dar care să ofere rezultatele într-un timp mai scurt decât metodele folosite în practica uzuală (microscopia şi cultivarea), aşa cum ar fi metodele de biologie moleculară.

Un alt aspect important al managementului cazurilor de TB îl constituie tratamentul instituit în momentul diagnosticului, dificultatea cea mai importantă în acest demers, fiind reprezentată de rezistenţa la antibiotice. Creşterea ratelor de monorezistenţă remarcată în studiul nostru este predictivă pentru creşterea ratei de tulpini MDR, deşi în momentul actual aceasta nu constituie un pericol imediat pentru regiunea noastră.

Evitarea extinderii circulaţiei tulpinilor MDR, corelată semnificativ cu eşecul terapeutic şi creşterea incidenţei TB, poate fi realizată prin introducerea în practica uzuală a metodelor de identificare rapidă a MDR, cum ar fi identificarea genelor de rezistenţă în genomul bacterian.

THE ROLE OF CAPSULE ENDOSCOPY IN SUSPECTED CROHN'S DISEASE (Abstract): Capsule endoscopy (CE) revolutionized the small bowel examination. We emphasize the role of CE in suspected Crohn's disease, studying 24 investigations performed in the Institute of Gastroenterology and Hepatology. The global diagnostic yield was 54%, the specific diagnostic yield for Crohn's disease was 37,5%, the specificity was 100% and the retention rate was 4,1%. For maximum accuracy and efficiency, unitary administration and diagnostic criteria are needed, and for minimising the risk of complications, specific prior investigations would be suitable. **Key words:** SUSPECTED CROHN'S DISEASE, CAPSULE ENDOSCOPY

La ora actuală nu există un test unic, standard, de diagnostic pentru boala Crohn, acesta bazându-se pe o combinaţie de elemente clinice, biologice, endoscopice, radiologice şi anatomopatologice. Clasic, imagistica bolii Crohn a fost reprezentată de endoscopia convenţională şi metodele radiologice de examinare a intestinului subţire (1). Videocapsula endoscopică (VCE), dar şi apariţia enteroscopiei cu balonaş au revoluţionat imagistica intestinului subţire, aducând contribuţii majore în diagnosticul, clasificarea, decizia terapeutică sau aprecierea prognostică a bolilor inflamatorii intestinale (2).

Studiul de faţă îşi propune să analizeze rolul videocapsulei endoscopice în evaluarea pacienţilor cu suspiciune de boală Crohn.

MATERIAL ŞI METODĂ

Am analizat pacienţii investigaţi cu VCE pentru suspiciunea de boală Crohn în Institutul de Gastroenterologie şi Hepatologie Iaşi în perioada 2004-2010.

Am analizat datele demografice ale pacienţilor, durata de la debutul simptomelor, tabloul clinic, investigaţiile anterioare, rezultatele la examinarea cu VCE, complicaţiile acesteia, evoluţia ulterioară şi confirmarea diagnosticului pacienţilor pe parcursul a minimum şase luni de urmărire.

REZULTATE

În perioada studiată, dintre cele 164 de investigaţii cu VCE efectuate în Institutul de Gastroenterologie şi Hepatologie, suspiciunea de boală Crohn a constituit indicaţia de administrare a VCE în cazul a 24 de pacienţi.

Date demografice. Şaisprezece pacienţi (66,7%) au fost de sex masculin şi 8 pacienţi (33,3%) de sex feminin. Vârsta s-a încadrat între 19 şi 55 de ani, cu o vârstă medie de 36 +/- 12 ani. Repartizarea pe grupe de vârstă a fost următoarea: sub 20 de ani: 1 caz, între 20 - 30 ani: 7 cazuri, între 30 - 40 ani: 6 cazuri**,** între 40 - 50 ani: 7 cazuri, peste 50 ani: 3 cazuri.

Caracteristici clinice. Suspiciunea s-a bazat în primul rând pe tabloul clinic, caracterizat de: durere abdominală**,** diaree cronică**,** scădere ponderală sau status subnutriţional**.** În unele cazuri s-au adăugat simptome sau semne suplimentare, precum: leziuni perianale, sindrom subocluziv în antecedente, masă abdominală palpabilă, artralgii, febră.

Tablou biologic. Au fost urmăriţi următorii parametri: anemie, markerii inflamatori precum viteza de sedimentare a hematiilor (VSH), proteina C reactivă (CRP).

Istoricul bolii a măsurat o medie de 8 +/- 3 luni. De menţionat că doi pacienţi prezentau antecedente semnificative, de enterectomie în urmă cu şase, respectiv zece ani.

Investigaţii imagistice anterioare. Toţi cei 24 de pacienţi au efectuat anterior administrării VCE, colonoscopie, în cinci cazuri completată de ileoscopie, nediagnostice. Tranzit baritat de intestin subţire a fost efectuat la trei pacienţi, un pacient prezentând aspect inflamator combinat cu leziuni ulcerative, un pacient prezentând doar aspect de afectare inflamatorie, iar un pacient neavând leziuni. Tomografia computerizată abdominală a fost efectuată la şapte pacienţi (29,1%), descriind leziuni ridicând suspiciunea de boală Crohn de intestin subţire la şase pacienţi (25%).

Criterii de excludere. Nu au fost investigaţi cu VCE pacienţii care au prezentat la examinări imagistice anterioare aspecte de stenoză sau strictură a tractului digestiv sau care prezentau anamneză sugestivă de sindrom subocluziv. Totodată, pentru a elimina rezultatele fals pozitive, a fost efectuată anterior administrării VCE o anamneză amănunţită privind medicaţia AINS; nici unul dintre pacienţi nu a avut istoric de consum de AINS în luna premergătoare evaluării cu VCE.

Rezultatele investigaţiei cu VCE

Pacienţilor le-a fost administrată videocapsula M2A PillCam SB2 Given Imaging, Yoqneam, Israel. Pregătirea a constat în ingestia a 2 litri de polietilenglicol (PEG) în seara dinaintea examinării, cu post minimum 8 ore înaintea investigaţiei. Ingestia capsulei s-a produs fără incidente.

Rata de vizualizare a intestinului subţire. În 17 (70.8%) cazuri examinarea intestinului subţire a fost completă, în timp ce în 7 (29.2%) cazuri capsula nu a atins cecul după cele 8 ore de tranzit. Cauzele au fost: viteza de tranzit lentă în 6 (25%) cazuri şi existenţa unei stenoze ileale împiedicând progresia capsulei într-un caz (4,1%), în care s-a înregistrat şi retenţia capsulei cu intervenţie chirurgicală consecutivă.

Leziunile au fost împărţite în: **leziuni minore (**congestie izolată, eroziuni sau ulceraţii în număr mai mic de trei, limfangiectazii, angiodisplazii) care nu au permis un diagnostic specific şi l**eziuni majore (**minimum trei ulceraţii sau ulcere, stenoze ulcerate, fistule, cazurile cu mucoasă cu vili şterşi, serată şi cu leziune protruzivă, parazitoză), care au permis formularea unui diagnostic endoscopic specific, şi anume: suspiciune de boală Crohn necomplicată

(trei cazuri), boală Crohn complicată cu stenoze (patru cazuri), boală Crohn complicată cu fistulă (două cazuri), boală celiacă necomplicată (un caz), suspiciune de boală celiacă complicată (un caz), modificări inflamatorii probabil postoperatorii (post-enterectomie) într-un caz, parazitoză intestinală (un caz). Unsprezece pacienți nu au beneficiat de un diagnostic în urma efectuării videocapsulei. La aceştia, tranzitul intestinului subțire s-a încadrat în cele 8 ore de înregistrare.

Randamentul diagnostic al VCE. A fost formulat un diagnostic la 13 din cei 24 de pacienți, randamentul diagnostic global al VCE fiind de 54%. Nouă (37.5%) pacienți din totalul celor 24 au fost diagnosticați cu boală Crohn. Au mai fost descrise elemente patologice, dar fără semnificație diagnostică, la trei pacienți (congestie parcelară a mucoasei, limfangiectazii duodenale la un pacient, diverticuli la un pacient, angiodisplazii la un pacient). Nu au fost găsite leziuni la un număr de 9 pacienți.

Complicații. S-a înregistrat un caz (4,1%) de retenție a capsulei, la un pacient cu multiple ulcere etajate şi stenoze ulcerate. Retenția a antrenat un sindrom subocluziv care a necesitat intervenție chirurgicală.

Urmărirea pacienților a durat între 6 luni şi 7 ani. Diagnosticul de boală Crohn a fost confirmat la toți cei nouă pacienți, fie chirurgical, fie prin evoluția favorabilă la tratamentul medical specific (derivați de 5-ASA, imunomodulatori sau agenți biologici). Pacientul suspectat de boală celiacă complicată a fost diagnosticat în urma enteroscopiei cu biopsie cu limfom B, evoluând ulterior nefavorabil. Pacientul cu aspect sugestiv de boală celiacă necomplicată a efectuat serologie şi biopsie duodenală cu confirmarea diagnosticului, evoluând favorabil la regim fără gluten**.** Pacientul cu parazitoză intestinală a efectuat tratament antiparazitar, cu normalizarea hemoglobinei şi ameliorarea simptomatologiei digestive.

DISCUȚII

A fost analizat un grup de 24 de pacienți suspectați de boală Crohn, pe baza unor criterii clinice, biologice şi/sau imagistice, cărora li s-a administrat VCE de intestin subțire după excluderea contraindicațiilor. Şaisprezece pacienți (76,7%) îndeplineau, opt din 24 pacienți (33,3%) nu îndeplineau criteriile Conferinței Internaționale de Capsulă Endoscopică de suspiciune a bolii Crohn (un simptom digestiv plus încă cel puțin un element dintre următoarele: fie un simptom extradigestiv - febra, artralgii, eritem nodos/pioderma, colangita sau CSP, fie rezultat imagistic anormal, fie markeri inflamatori). Rata de diagnostic a fost semnificativ mai mare la pacienții cu criterii ICCE față de cei care nu le îndeplineau (75% versus 12,5%), asemeni altor studii (3,4). Aceasta susține utilitatea algoritmului în păstrarea raportului cost-eficiență.

Randamentul diagnostic global al videocapsulei a fost de 54%, iar randamentul în boala Crohn suspectată a fost de 37,5%, ceea ce încadrează seria noastră către limita inferioară a valorilor din literatură, încadrate între 33% şi 70% (5). Explicațiile pot fi: laxitatea criteriilor de administrare a videocapsulei (inclusiv la cerere) şi neincluderea în calcul a cazurilor în care s-au descris leziuni certe, dar care nu explicau simptomatologia (limfangiectazii, polipi duodenal, angiodisplazie). Includerea acestora ar fi însumat 17 cazuri cu leziuni diagnostice, corespunzând unui randament

mai mare, de 70.8%. La 11 (45,8%) din pacienții explorați, videocapsula fie a evidențiat leziuni minore, fie nu a descris nici o leziune. Evoluția clinică ulterioară a fost favorabilă sub tratament simptomatic sau specific pentru tulburări funcționale intestinale. Astfel, acest procent nu trebuie privit ca risipă de resurse, rezultatul negativ evitând costuri exploratorii ulterioare.

Videocapsula este o tehnică pur vizuală; nu există posibilitatea unor manevre externe care să ajute vizualizarea sau a prelevării de biopsii sau efectuării de acte terapeutice. Acestea ar putea constitui factori de influență negativă asupra randamentului diagnostic şi asupra specificității metodei.

Specificitatea VCE a fost de 100%, la toți pacienții suspectați în urma investigației cu VCE cu boală Crohn fiind confirmat ulterior diagnosticul, prin chirurgie şi examen histopatologic (trei pacienți) sau prin evoluția clinică (şase pacienți). Nu există un standard diagnostic pentru boala Crohn. Mow (6) a propus un minim de 3 eroziuni sau ulcerații, iar Voderholzer (7) minimum zece leziuni aftoide. În prezent, cea mai largă utilizare are propunerea lui Mow, adoptată şi în studiul de față. Leziuni minore precum edemul vililor, eritem parcelar, hiperplazie limfoidă, limfangiectazii, deşi considerate în unele studii ca manifestări precoce ale bolii Crohn, nu au fost considerate diagnostice. Specificitatea maximă se poate explica prin rigurozitatea în interpretarea leziunilor evidențiate şi formularea diagnosticului de boală Crohn pe bază vizuală.

Pacienții cu diagnosticul confirmat clinic au fost urmăriți o perioadă suficientă de timp (minimum 6 luni). Astfel, a fost evitat riscul diagnosticelor fals pozitive.

În studiul nostru, 29% din examinări au fost incomplete, dar toate s-au înregistrat între pacienții cu leziuni, putând atrage atenția asupra unor factori de influență negativă asupra vitezei de progresie a videocapsulei precum stenozele, cu acumulare de lichid la nivel suprajacent.

Complicațiile au fost reprezentate de un caz (4,16%) de retenție a capsulei, care a necesitat intervenție chirurgicală, în a zecea zi post-ingestie. Frecvența retenției depinde de populația studiată (8), prin indicația de administrare a videocapsulei şi selecția pacienților, variind între 0 şi 21%, cu incidență globală de 1-2% (9-11). Rata de retenție din studiul nostru se corelează celei din boala Crohn suspectată, care variază între 0 şi 5% (11) Clasic, boala Crohn suspectată constituia o contraindicație pentru videocapsulă, prin potențialul de impactare. Recent multiple studii susțin utilitatea videocapsulei şi în suspiciunea de boală Crohn (12-14), păstrând prudența prin efectuarea anterioară de investigații care să excludă obstrucția.

CONCLUZII

Randamentul diagnostic al videocapsulei de intestin subțire administrată în cazurile suspectate de boala Crohn intestinală a fost de 37.5%. A fost înregistrată o rată a complicațiilor de 4.16%. Pentru un diagnostic de acuratețe maximă, este nevoie de stabilirea unor criterii unitare şi bine definite. Pentru a creşte randamentul diagnostic şi cost-eficiența, este nevoie de aplicarea unor criterii de selecție mai riguroase, iar pentru a minimaliza rata complicațiilor, se impune prudență în administrarea videocapsulei in prezența suspiciunii de stenoză intestinală, cu efectuare prealabilă de alte investigații noninvazive care să excludă obstrucția.

PULMONARY REHABILITATION IN COPD PATIENTS-OBSERVATIONAL STUDY **(**Abstract): The **aim** was to analyze the effects of an 8-week pulmonary rehabilitation (PR) program on quality of life (QoL), physical performance (6MWD value - six-minute walk test) and pulmonary function in patients with mild and moderate COPD. **Material and methods:** 23 subjects with COPD with FEV1≥50% were assigned to a clinic treatment group (n=12) or a home exercise group (n=11). Subjects in the first group received supervised exercise program over a 6-week period after 2 weeks inpatient PR program. Subjects in the second group received the same exercise program initially in hospital, followed by 6 weeks of home exercises, reinforced by a clinic visit at 2 weeks. Measured outcomes were the 6MWD, the generic QoL scale St. George's Respiratory Questionnaire Disease (SCRQ) and statistical analysis by ANOVA test. **Results:** Both groups showed clinically and statistically significant improvements in 6MWD and SCRQ scores at 8 weeks; improvements were still evident in both groups at 3 months. By 8 weeks, SGRQ scores had improved in both groups with 28% and 24%; 6 MWD had improved with 13% and 5%, and important differences were observed in the mean changes of 6MWD: 56.42 m in the first group, 17.7 m in the second group. At 3 months, the results of both groups were substantially and about equally improved over baseline measurements. **Conclusions:** Subjects in the first group were more satisfied with the overall outcome of their rehabilitation treatment compared with subjects in the second group. **Keywords:** PULMONARY REHABILITATION, COPD, QUALITY OF LIFE, PHYSICAL PERFORMANCE, PULMONARY FUNCTION.

Chronic Obstructive Pulmonary Disease (COPD) is "a common preventable and treatable disease, characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases" (1). COPD patients must face limitations in daily activities and reduced quality of life (QoL) caused by dyspnea, airflow limitation, skeletal muscle dysfunction and comorbidities (1, 2, 3, 4, 5). The major

goals of stable COPD management are to reduce symptoms, increase participation in daily living activities and improve health-related quality of life (HRQoL) (1, 2, 3, 6). The pharmacological treatment of COPD is main target is to reduce the degree of airflow limitation and there is evidence that FEV1 has a relatively poor correlation with symptoms, HRQoL and daily functioning (7, 8, 9).

American Thoracic Society (ATS) and European Respiratory Society (ERS) recommendations for the management of COPD are to use of pulmonary rehabilitation programs (PRPs) for all groups of risk of the illness (A, B, C, D), especially self-management techniques to improve exercise tolerance and HRQoL, and to reduce symptoms like dyspnea and fatigue (1, 2, 10, 11).

PRPs have been shown not only to improve exercise capacity and health status and to reduce dyspnea and but also to diminish the use of healthcare resources (2, 6, 12-18).

We carried out a comparative study single blind to analyze the effects of an 8 weeks rehabilitation program on dyspnea, HRQoL, physical performance and pulmonary function in patients with mild and moderate COPD (19, 20).

The aim of the study was to evaluate functional capacity and health status at 8 weeks of physical treatment and at 3 months after conclusion of PRP in patients regularly followed in respiratory health services.

MATERIAL AND METHODS

All patients with a confirmed diagnosis of COPD with FEV1>50% admitted to a PRP at Physical Medicine and Rehabilitation Department, Hospital No. 2, Craiova, between January 2018 and May 2018 were recruited (tab. I). The diagnosis of COPD was made according to GOLD definition and classification (1, 7, 9). All patients received pharmaceutical treatment according with COPD GOLD stage. The respiratory specialist oversaw confirming the diagnoses, treatment and verifying exclusion criteria.

PRP of mild/moderate COPD patients included: the patient selection and initial evaluation, the goal developing, the ensuring the smooth running of the program, the evaluation of patient outcomes, the performing of long/term follow-up.

On admission, patients were excluded from this study if they had a diagnosis of other pulmonary disease, with unstable cardiac conditions, neuromotor limitation or COPD patients with a recent exacerbation (in the preceding 4 weeks).

TABLE I

The main characteristics of the study patients

	Study group 1 (G1)	**Study group 2 (G2)**
No of patients	12	11
Gender	10 M / 2 W	8 M / 3 W
Mean age	46 (±8) years old	48 (±7) years old
Own place	7 V, 5 T	6 V, 5 T
Smokers	13	10
Tobacco index (mean)	23 PA	26 PA
Onset of COPD (mean)	3.2 years	4.4 years
FEV 1 initial	65.5 %	67.82 %
W = women, M = men, V = village, T = town		

Study design

The study design as a flow diagram: pre-to-post comparisons were made in those patients (fig. 1).

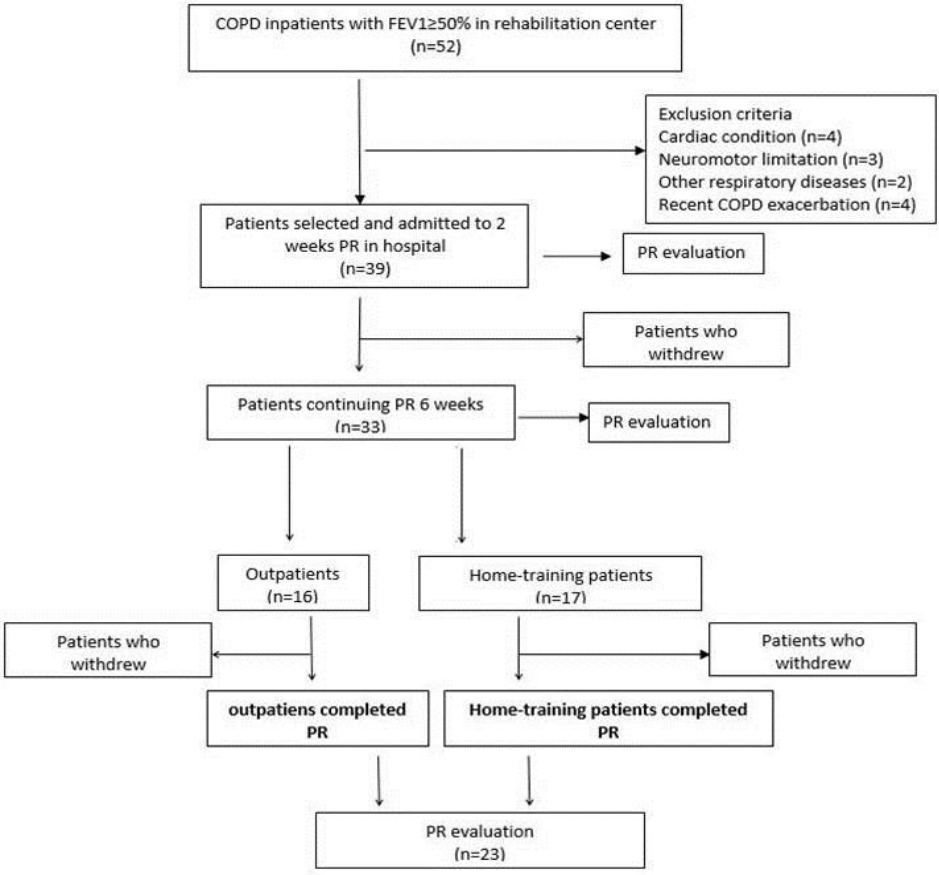

Fig. 1. A flow diagram of study design

The patients with mild and moderate COPD were begun 8 weeks of PRP in the hospital. Sessions were supervised by a rehabilitation therapist. According with patient's preference and to the probability that patient maintain the exercise at home, patient was randomized in two study groups. Both groups started PRP in hospital for 2 weeks. After, the study group (G1) - received supervised exercise in hospital (outpatient PRP). The second group of patients (G2) received the same exercise program initially - in hospital, followed by 6 weeks of PRP at home residence, reinforced by a clinic visit at 2 weeks.

We performed a complete history, physical examination, chest radiography, laboratory and pulmonary function data. The studied parameters were:

- dyspnea - using Medical Research Council (MRC) scale (16);
- pulmonary lung function: FEV1 and FEV1/FVC % using a spirometer (Vitalograph) connected to a computer, for a data analysis (1,8,9);
- exercise capacity: six-minute walking distance (6 MWD) according to the ATS Guidelines (17);

- QoL using St. George's Respiratory Questionnaire Disease (SGRQ) - a standardized, self-administered questionnaire for measuring impaired health and perceived HRQL in airways disease (21, 22).

All evaluations were performed by the pulmonary physician, without knowing the location of the PRP. Patients were able to perform the inpatient (2 weeks) and outpatient (6 weeks) RPPs. The size of group at any session was limited to 5 patients.

The rehabilitation methods we used were: monitoring pharmacotherapy, education 15 minutes daily sessions (breathing retraining, energy conservation, nutritional and medication education, smoking cessation, teaching the patients how to cope with feelings of dyspnea), physical training and educational and psychological management. The second part was devoted to physical training, preceded by Jacobson's technique, for twice-daily, 3 days a week, for eight weeks, 30-minute sessions, at 75 - 80% of the load achieved on the incremental pre-exercise test carried out at enrollment, and consisted of:

- respiratory muscle training - inspiring against a closed glottis, pursed lips breathing, expiratory abdominal augmentation and synchronization of thoracic and abdominal movements;
- modified proprioceptive neuromuscular training (four periods with 5 minutes of repetitive large muscle dynamic exercise separated by 1 minute with mild exercise), including stretching as part of the warm-up period and of the cool-down, respectively;
- complete lower extremity aerobic training on a cycle ergometer (Aerobic 2100) / the morning session; training workload was assessed daily in the inpatients and weekly in the outpatients.

After 2 weeks of inpatients PRP, the patient of G1 continued physical therapy in hospital 3 days a week like outpatient PRP. The patient of G2 continued PRP at home.

The study was approved by the Ethics Committee of the University of Medicine and Pharmacy Craiova and was carried out in concordance with the World Medical Association Declaration of Helsinki (2000). We have obtained informed consent from our patients for the treatment and for their medical data to be used in a study.

Statistical analysis

Data are presented as mean ± standard deviation for continuous variable and percentages for categorical variables. The difference between means was determined using Student's t-test. Differences parameter values between groups were tested by ANOVA test. A p-value <0.05 was considered statistically significant. The statistical analysis was performed using *SPSS 8.0* for Windows; SPSS Inc., Chicago, IL, SUA and applied according to the current methodology.

RESULTS

After 8 weeks of PR all subjects reduce dyspnea - we obtained a fall in breathlessness mean score, had a significant, albeit small, improvement in mean FEV1, extended exercise endurance (6 MWD increased significantly), enhanced HRQoL (we considered 4 points as minimal clinically important difference as stated by Paul Jones), reduced use of pharmacological agents (tab. II).

For G1 we did not identify any significant difference between the mean values for FEV1 measured at three points (p ANOVA = 0.759> 0.050). Spirometry showed at all patients, especially in younger, small increases in FEV1 after 8-week

inpatient PR. At 3-month FEV1 increased at 67.83 %. For G2 we did not identify any significant difference between the mean FEV1values at three points (p ANOVA=0,913>0,050); spirometry showed small increases in FEV1 after 8-week PR (FEV1=69.05%) compared to initial (FEV1=68.8%). For FEV1 we have identified no statistically significant difference between G1 and G2 (tab. II).

TABLE II

Results of PRP in the two-study group

Parameter	Study group	Baseline				After 8-week rehabilitation				After 3 months			
		Mean	Std.dev.	CI.95%	p	Mean	Std.dev.	CI.95%	p	Mean	Std.dev.	CI.95%	p

For G1, we obtained a fall in breathlessness mean score (MCR scale) with 45% of the initial score after 8 weeks; we identified a significant difference at the boundary between the MRC mean values to three times (p ANOVA = 0.049 <0.050). In the G2, MCR mean score decreased with 38% after 8 weeks, but at 3 months was decreased only with 12%, without significant difference between the mean values (p ANOVA = 0.553> 0.050). We have identified a statistically significant difference only for the initial investigation (p = 0.010 Student <0.050), between G1 and G2.

For G1, we identified a significant difference between the mean values measured for SGRQ at three points (p ANOVA = 0.007<0.050). At the end of PRP there was an improvement in health status in both groups. At 8 weeks in G1, mean SGRQ score increased with 28% and with 24% in 3 months after PRP compared by baseline (tab. II). On the contrary, in G2, if at 8 weeks SGRQ score was better that before PRP with 26%, there were changes in total SGRQ score, with a tendency to get worst at 3 months after PRP, when the mean SGRQ score was increased only with 7%

compared by baseline (tab. II). Comparing the results between G1 and G2 we have not identified at any of the three points, any statistically significant difference.

After PRP, in the G1, mean 6MWD was clinically and statistically significant increased at 8 weeks (+13%) (tab. II). We identified a significant difference between the mean 6MWD values at three points for G1 (p ANOVA = 0.001<0.050). In G2, mean 6MWD was increased at 8 weeks (+17.7m =5%) compared with initial values. After completing PRP inpatient, 6MWD was increased only with 2% compared with baseline (tab. II). For G2 did not identify any significant difference at three points (p ANOVA = 0.840> 0.050). Comparing the results between the two groups we have not identified at baseline, a statistically significant difference, but the investigation of the second and the final difference between the two groups became statistically significant difference (the end p Student = 0.003, the intermediate p Student = 0.012).

Although all parameters studied had a favorable evolution, when we performed linear regression equation for the mean initial values and intermediary, respectively final values of the studied parameters, we found that initial value are predictive for both intermediary and final values only in G1 (fig. 2, 3, 4).

DISCUSSION

The benefits of the PRP in the management of patients with chronic respiratory disease already known and well-established (1, 2, 3, 6-12, 14, 15), were also observed in this study. The studies published so far in the literature show the positive effects rehabilitation has in patients with moderate to severe (23, 24), very severe COPD (25) or comorbidities (26).

The present study highlights the benefits of PR in patients diagnosed with COPD with FEV1> 50% without comorbidities, rehabilitation initially performed under hospital conditions, then at home. In both groups, after PRP, patients showed improvement in health status and but not in functional capacity.

Studied patients have carried out a PRP during two weeks in hospital treatment, followed by six weeks at home (G2) or hospital (G1). 2017 GOLD appreciates the minimum duration of an effective PRP is at least 6 weeks, the effectiveness increases with increasing duration (1). Our program duration was greater than the minimum recommended two weeks of GOLD 2014 and the British Thoracic Society (6 weeks) (27). Compared with other studies (24, 25), the duration of the program is average, and there are programs for 4 weeks or three years (23), in moderate-severe COPD (24), and 26 weeks for patients with severe ventilatory dysfunction (25). Other studies evidenced that longer programs seem to enhance long-term effects (23, 28).

Initiation of the program was carried out under hospital conditions, which is considered necessary given the fact that patients have never carried out such a program and requiring the careful monitoring of respiratory function during exercise. Subsequent completion (out-patient and home-training) was done to capture the effects of PR in the two situations. We mention that carrying home-training program was accepted in patients who did not have easy access to the out-patient services. In the literature we didn't find any studies we could refer to, the more often patients performing an outpatient PRP (24, 25, 29).

The limited number of patients compared to other studies (25, 30, 31), is explained by the inclusion only patients with FEV1>50%, without comorbidities and poor adherence for this form of non-pharmacological treatment. We do not have an explanation for the poor adherence of G2 to the PRP, as both groups were similar in terms of baseline clinical and demo-

graphic characteristics and similar PRP benefits in both groups (tab. I). Translation of the acquired skills to patient's lifestyle may be prevented by different barriers: lack of self-confident, cognitive impairment and behavioral issues, lack of motivation and the presence of physical barriers at home or in the community (25, 32).

The G2 poor adherence to follow-up testing could be explained by the fact they were also less compliant to exercise. A possible explanation for the worst long-term results with patients that did cycling during PRP, could be the difficult maintaining this exercise regularly at home and consequently they became less active.

We mention that most patients with COPD have a respiratory function with a severe or very severe reduction (FEV1 < 50%), highlighting the absence or ineffectiveness of programs for early detection of smoking-induced pathology or respiratory hazards. Most patients included in the study came from rural areas.

Unlike other studies in which correlations are made between respiratory function parameters (29, 30, 31), in our study we followed the recovery program effects on pulmonary function, exercise capacity (6MWD), dyspnea (MRC) and quality of life (SGRQ) after 6 weeks of rehabilitation and three months after the end of the program. In our study we didn't set out to achieve a target intensity of 80% of peak work rate but strived that in the first 2 weeks of the rehabilitation program, patients would learn a correct respiratory pattern (4 stage), with physical effort during exhale.

For FEV1 parameter we cannot appreciate an improvement percentage, given the irreversible character of the lesions and respiratory function degradation in COPD, regardless of the therapeutic method applied.

6MWD values were in the concordance with the literature (29, 31). The improvement of 6MWD after the rehabilitation was higher compared with other published results (29,31). This is because our patients perform daily physical exercises; most of them come from rural areas. Also, our patients were complaining to proprioceptive training.

Like other literature data (33) our results confirmed that regular aerobic exercise is associated with minimal increase in overall health status and walking self-efficacy, expressed through 6 MWD, as well as a reducing progression of dyspnea, especially during activities of daily living effort.

After 12 weeks the results of PR program are decreasing, similar another publication (34), perhaps due to limiting interest for constant and daily proprioception training. As limitations of this study we can consider the small number of patients, the short duration of follow-up phase, compared with other studies (35, 36) and lack of comorbidities. Poor adherence has a detrimental effect on morbidity, mortality and health care resources (37).

In appropriate future, PRP in Romania should become a current medical option in all disabled patients, so the mentioned limits will be eliminated.

CONCLUSIONS

The results of the present study show that the proprioception is fundamental for sensory/motor control over thorax joint stability, so our proprioceptive neuromuscular training offers optimal control of respiratory movements and is essential in patients with COPD.

Combining in-patient / out-patient or in-

patient / home-training is an optimal way in which the patient with COPD with FEV1>50% improve their exercise capacity and Qol.

Based on the results of this study, there is a need for more research on this subject. We consider that chest stretching and adapted neuromuscular training represent two important educational needs of an individual COPD patient management.

CONSIDERATIONS BASED ON THE ETIOLOGY OF ACUTE RENAL FAILURE IN CHILDREN (STUDY ON 110 CASES) (Abstract) : The Article highlights the fact that without a homogeneous definition of acute renal injuries of adults and infants, for the last 5 years a new classification system has appeared. The RIFLE pediatric criteria are looked over, validated in 2007 which allow a better IRA classification at infants and allow comparisons between the intensive care units and also allow assumptions on the predictions of the disease. The list of certain causes of IRA at infants is rendered, the genetic background of children with IRA risk is highlighted, the necessity of reevaluating and criteria of evaluating renal functions is underlined. The etiology of renal failure was studied on 110 infants interned on a period of 5 years (2003- 2008) in 2 centers with different profile : The Clinic Of Pediatric Nephrology "Sf. Maria" Iaşi and the Intensive Care Compartment of The Pediatric Hospital "Sf. Ioan" Galaţi.
Keywords : ACUTE KIDNEY INJURY, CHILD, ACUTE RENAL FAILURE

Insuficienţa renală acută, cunoscută în prezent ca leziune renală acută, rămâne o problemă semnificativă în pediatrie, prin evoluţia sa, de multe ori devastatoare.

Incidenţa acestei afecţiuni este în creştere şi etiologia sa în ultima decadă s-a schimbat prin predominanţa bolilor renale de cauza multifactorială, în general la copiii polispitalizaţi (1, 2, 6). Există factori genetici care predispun anumiţi copii la leziune renală (polimorfismul genei enzimei de conversie, polimorfismul genei factorului de necroză tumorală, a interleukinei-1, 6, 10, variaţiile genetice ale proteinei de şoc termic 72) (2).

Este în general acceptat că leziunea renală acută este caracterizată prin insuficienţa rinichiului de a regla homeostazia adecvată a fluidelor, electroliţilor şi acido-bazică, prin creşterea producţiei de azot în asociere cu creşterea creatininei serice (la valori mai mari cu 50% faţă de nivelul bazal) şi, în multe cazuri, cu reducerea concomitentă a diurezei.

În literatură există peste 30 de definiţii, multe dintre ele bazate pe nivelul creatininei serice (2,3,4). Concentraţia creatininei serice poate avea variaţii mari, în funcţie de vârstă, sex, masă musculară, metabolismul muscular şi starea de deshidratare (3,5,7). Ea poate să nu fie crescută până când aproximativ 50% dintre nefroni au fost pierduţi.

La pacienţii cu leziune renală acută, schimbările precoce ale funcţiei renale, manifestate prin creşteri mici ale creatininei serice ce reflectă o leziune renală semnificativă şi

TABELUL I
Criteriile pediatrice RIFLE

Criteriul	Estimarea Cl. la creatinina	Diureza
Risk	Cl.creat ↓ cu 25 %	< 0.5 mL/ Kg/h pentru 8 h
Injury	Cl.creat ↓ cu 50 %	< 0.5 mL/ Kg/h pentru 16 h
Failure	Cl.creat ↓ cu 75 % Cl.creat < 35 mL/min/1.73m^2	< 0.3 mL/ Kg/h pentru 24 h sau anurie pentru 12h
Loss	Insuficienţă persistentă > 4 săpt	
End stage	Insuficienţă persistentă > 3 luni	

care se asociază cu o înaltă morbiditate şi mortalitate. Creatinina serică nu este un indicator fidel al funcţiei renale şi din cauza altor comorbidităţi la pacienţii trataţi precum şi datorită creşterii sale tardive, ceea ce face aproape imposibilă stabilirea debutului insuficienţei renale acute (2, 5, 10, 11). Întârzierea diagnosticului determină întârzierea terapiei. Este ştiut faptul că restabilirea fluxului sanguin renal previne instalarea leziunilor renale ireversibile şi, deci, în multe cazuri diagnosticul precoce poate schimba cursul bolii.

Lipsa unei definiţii uniforme si multidimensionale (2, 8, 10, 11) a făcut ca insuficienţa să fie recunoscută ca o leziune renală semnificativă iar întârzierea tratamentului şi incapacitatea de a generaliza rezultatele unui singur studiu să ducă la necesitatea unei clasificări sistematice.

Noul sistem de clasificare (4, 15) intitulat criteriile RIFLE (R - risc pentru disfuncţie renală ; I - injurie, leziune renală ; F - failure, insuficienţa funcţiei renale ; L - loss, pierderea funcţiei renale ; E - end stage kidney disease, stadiul final al bolii renale) a fost propus pentru standardizarea clasificării insuficienţei renale acute la adulţi, în 2004 de grupul ADQI (Acute Dyalisis Quality Initiative).

Criteriile RIFLE au arătat, prin studii multinaţionale şi multicentrice, predicţia indiferent de durata internării, cost, morbiditate şi mortalitate (2, 4).

Criteriile Pediatric RIFLE, folosite pentru clasificarea mai bună a insuficienţei renale acute reflectă cursul leziunii renale la copiii admişi în unităţile de terapie intensivă (4, 6).

Criteriile RIFLE pediatrice au apărut pentru o mai bună caracterizare a leziunii renale şi au fost validate la copii, permiţând comparaţii între centre. Criteriile RIFLE au fost utilizate de AKIN, un grup de nefrologi pentru adulţi, nefrologi pediatri, reanimatori şi terapeuţi organizaţi într-o societate interesată de cercetări în domeniul insuficienţei renale, accesul fiind facilitat internaţional, interdisciplinar şi prin colaborare între societăţi. În 2007 s-a modificat scorul RIFLE pediatric, introducându-se predicţii ale creşterii costurilor, creşterii duratei de spitalizare, mortalităţii şi necesitaţii terapiei de substituţie renală la pacienţii pediatrici din unităţile de terapie intensivă. Stabilirea criteriilor p-RIFLE implică studii prospective multicentrice, similare cu ale grupului registrului de prospectivă pediatrică pentru terapia de substituţie renală (7,8).

Folosirea formulei lui Schwartz pentru estimarea leziunii renale acute este mai adecvată pentru pacienţi peste 30 de ani. A fost stabilită nouă ecuaţie Schwartz pentru determinarea GFR la copii (=0,4 x T/ creatinină serică).

În prezent este necesară revizuirea ghidurilor şi criteriilor pentru evoluţia funcţiei renale, inclusiv Pediatric RIFLE.

Este nevoie urgent de utilizarea unor

TABELUL II
Etiologia leziunii renale acute
(după Sharon Phillips Andreoli. *Pediatric Nephrol*. 2009, 24, 253-263)

Tipul	Etiologie
Leziunea prerenală	Scăderea volumului intravascular "adevărat" Scăderea efectiva a volumului intravascular
Boli renale intrinseci	Necroza tubulara acuta (nefropatia vasomotorie) Agresiunea hipoxic-ischemică Indusa de droguri Mediata de toxine - toxine endogene: hemoglobina, mioglobina - toxine exogene: etilenglicol, metanol Nefropatia urică şi sindrom de liza tumorala Nefrita interstițială: - indusă de droguri - idiopatică Leziuni vasculare: - tromboza arterei renale - tromboza venei renale - necroza corticala - SHU Hipoplazia ± displazie - idiopatică - expunerea la droguri nefrotoxice
Uropatiile obstructive	Obstrucție pe rinichi unic Obstrucție bilaterală ureterală Obstrucție uretrală

noi marcheri sensibili si specifici (9) pentru leziunea renală acută: NGAL, molecula 1 de leziune renală (kim 1), interleukina 18, cystatin C. Aceştia apar la scurt timp după producerea leziunii şi este posibil ca valorile lor să fie folosite în timpul leziunii iniţiale şi în perioada de evoluţie a insuficienţei renale. Bazându-ne pe diferenţierea expresiei biomarcherilor este posibil ca aceştia să facă distincţia între variate tipuri şi etiologii ale insuficienţei renale acute.

Apariţia biomarcherilor precoce de leziune renală şi noua clasificare sunt necesare pentru iniţierea strategiei terapeutice de succes în insuficienţa renală.(2, 9)

În ultima decadă s-a schimbat atât epidemiologia insuficienţei renale acute, cât şi accesul la tratament, au apărut tehnologii rafinate şi echipament de monitorizare complex, precum şi modificări în structura etnică a populaţiei (12,13).

Cele mai frecvente cauze sunt enumerate în tabelul următor (2).

MATERIAL ŞI METODĂ

S-a urmărit structura etiologică a leziunii renale acute la 110 pacienţi de vârsta pediatrică internaţi pe o perioada de 5 ani în două spitale cu profil diferit:

- Clinica de Nefrologie Pediatrică Sf. Maria, Iaşi – lotul A, 51 de cazuri;

TABELUL III
Etiologia insuficienţei renale pe cele 110 cazuri

Etiologie	Nr. cazuri	Procente
Ischemie prerenală	44	40

2.	I	31	28
3.	F	41	37

- Compartimentul de Terapie Intensivă Pediatrică a Spitalului "Sf. Ioan", Galaţi – lotul B, 59 de cazuri.

Copiii au fost diagnosticaţi conform criteriilor RIFLE pediatrice, determinându-se Cl. la creatinina după formula lui Schwartz modificată. În 62 de cazuri a fost greu sau imposibil să se demonstreze oliguria sau anuria (diureza <500 ml la copii mari sau <1 ml/kg/h la copii mici si sugari), astfel că în numai 48 de cazuri a fost posibilă monitorizarea diurezei. O motivaţie ar fi dificultatea de recoltare a urinei la grupa mică de vârstă, lipsa unor dispozitive colectoare, evoluţia rapidă şi diagnosticul tardiv al bolii.

Anamneza, examenul fizic şi examenele de laborator (inclusiv examenul de urină şi examenele imagistice) au stabilit etiologia insuficienţei renale.

REZULTATE

Se observă predominanţa cauzelor prerenale, urmate de insuficienţa organică multiplă şi sindromul hemolitic uremic.

Grupul intoxicaţilor a cuprins: etilenglicol 1 caz, algocalmin 2 cazuri, paracetamol 1 caz, ciprofloxacin 1 caz, aspirina 1 caz, ciuperci 1 caz, substanţe detoxifiante 1 caz, nitriţi 1 caz.

Se observă la acest lot că predomină copiii în stările critice, în special cei cu insuficienţă organică multiplă, SHU şi intoxicaţiile. Insuficienţa organică multiplă s-a complicat în 9 cazuri cu insuficienţă renală acută şi în trei cazuri insuficienţa renală acută a evoluat spre insuficienţă organică multiplă.

În al doilea lot cea mai obişnuită cauza de leziune renală acută în copilărie este depleţia volemică şi aceasta poate fi prevenită, prin diagnostic şi tratament precoce.

Am observat asocierea cu un mare număr de comorbidităţi, mai ales la grupa a doua, în cazul sindroamelor de deshidratare.

Din totalul de 110 cazuri, la 25 de cazuri etiologia leziunii renale acute a fost multifactorială, agresiunea hipoxic-ischemică şi nefrotoxicitatea având o contribuţie importantă.

TABELUL V
Etiologia in lotul A

Etiologie	Nr. cazuri	Procente
Ischemie prerenală	9	8.1
Suferința organica multiplă	12	10.9
SHU	11	10
Intoxicații	9	8.1
Uropatii obstructive	4	3.6
Rinichi polichistic	1	0.9
Boli renale primitive	3	2.7
Litiază	1	0.9
Şoc hemoragic	2	1.7

TABELUL VI
Etiologia in lotul B

Etiologie	Nr. cazuri	Procente
Ischemie prerenală	35	31
Suferința organică multiplă	7	6.3
SHU	1	0.9
Intoxicații	2	1.7
Uropatii obstructive	3	2.7
Rinichi polichistic	1	0.9
Boli renale primitive	2	1.7
Litiază	2	1.7
Şoc hemoragic	3	2.7
Rabdomioliză	1	0.9
Limfom malign	2	1.7

Am constatat următoarele comorbidităţi :

- Sindrom Down 3 cazuri,
- Hidranencefalie 1 caz,
- Mielingomielocel 2 cazuri,
- Hidrocefalie 2 cazuri,
- Keilognatopalatoschizis 2 cazuri,
- Malformaţii cardiace 5 cazuri,
- Paralizie cerebrala infantila 3 cazuri,
- Microcefalie 2 cazuri,
- Mucoviscidoza 1 caz.

În ceea ce priveşte evoluţia 20 de cazuri au decedat şi la 15 cazuri evoluţia a fost spre boală renală cronică. Mortalitatea a fost mai mare în lotul B (16 cazuri), dar decesul s-a produs de obicei prin altă cauză decât cea renală. Ştiut fiind că acei copii care au suferit o leziune renală au riscul mai târziu de a dezvolta o boală renală cronică, toţi pacienţii din loturile noastre au fost chemaţi la control clinic, al tensiunii arteriale şi al examenului de urină pentru decelarea microalbuminuriei, dar s-au prezentat numai 25 %.

DISCUŢII

Global, leziunea renală acută are o contribuţie semnificativă la morbiditatea şi mortalitatea copiilor în stadii critice, în special la cei cu insuficienţă organică multiplă. Distribuţia epidemiologică a leziunii renale acute pediatrice variază în funcţie de tipul instituţiei care raportează rezultatele (11, 12, 13). Unele unităţi, conţinând un mare număr de traume chirurgicale, cum ar fi chirurgia cardiacă, raportează un număr mai mare de pacienţi pediatrici cu leziune renală decât centrele mai puţin dezvoltate (6, 8). Hui-Stickle şi colab. au arătat o creştere dra-

matică a leziunii renale acute pediatrice (18).

Înainte de 1990, cauzele cele mai frecvent citate erau : sindromul hemolitic uremic, *sepsis*-ul şi arsurile (2). Acum în ţările dezvoltate cea mai frecventa cauză este insuficienţa organică multiplă, (incluzând bolile congenitale cardiace), necroza tubulară acută, medicamentele nefrotoxice şi *sepsis*-ul (14, 16). În ţările dezvoltate SHU continuă să fie raportat ca una din primele cauze ale insuficienţei renale pediatrice.

Alte cauze de leziune renală, cum ar fi glomerulonefrita rapid progresivă pot prezenta leziune renală rapid evolutivă spre boala renală cronică.

Mai multe boli renale, cum ar fi : SHU, purpura Henoch-Schonlein şi uropatiile obstructive, asociate cu displazie renală, pot prezenta leziune renală cu funcţie renala normală sau aproape normală. La copii, funcţia renală poate fi puţin deteriorată, ducând la insuficienţă renală cronică după mai multe luni sau după mai mulţi ani, uneori la vârsta de adult.

Dacă în lotul nostru de 110 de copii predomină cauzele prerenale, urmate de *sepsis* şi de SHU, în raportul lui Bunchman- 2001, pe 226 de copii dializaţi acut, cauzele cele mai frecvente au fost bolile congenitale de cord, urmate de necroza tubulară acută şi de *sepsis* (17).

Raportul lui Goldstein din 2005 arată că cele mai frecvente cauze de IRA au fost în necroza tubulară acută şi medicaţia nefrotoxică iar bolile renale primitive apar doar în 7% din cazuri (18).

Două studii din regiuni diferite din Kenya au raportat de asemenea predominanţa etiologiilor prerenale la copil (2).

CONCLUZII

Cu toate progresele obţinute în terapia intensivă şi în terapia de substituţie renală IRA rămâne o boala cu o înaltă mortalitate.

Este o entitate comună în centrele de urgenţă, medicilor din aceste unităţi revenindu-le un rol decisiv în recunoaşterea precoce, în prevenirea leziunilor iatrogene şi în modificarea cursului bolii.

Există o strânsă relaţie între insuficienţa multiorganică şi mortalitatea intraspitalicească din bolile severe. O abordare mai dinamică a stării critice de boală, având ca scop identificarea pacienţilor cu risc, înainte de a se instala disfuncţia organică este, în mod cert, mai puţin costisitoare decât încercarea de a salva pacienţii *in extremis*.

Un index de prognostic uşor de folosit în camerele de gardă poate înlesni intervenţia precoce, cu o evoluţie mai bună şi cu un cost mai redus.

Recunoaşterea promptă şi la timp a bolii precum şi îndrumarea spre medicul nefrolog a fost postulată ca având drept rezultat, în multe cazuri, vindecarea pacienţilor cu IRA.

Este necesară revizuirea ghidurilor şi a criteriilor pentru evoluţia funcţiei renale.

Este nevoie de utilizarea unor marcheri sensibili şi specifici pentru leziunea renală, evaluările lor putând fi folosite în timpul agresiunii iniţiale dar şi în perioada de evoluţie a bolii, realizând distincţia între variate tipuri şi etiologii ale bolii.

STROKE-A POSSIBLE ADVERSE EFFECT OF COMBINATION THERAPY WITH PARITAPREVIR/RITONAVIR/OMBITASVIR + DASABUVIR. CASE REPORT (Abstract): The development of direct-acting antiviral agents against hepatitis C virus has revolutionized the management and control of this important liver disease. Combination therapy with paritaprevir/ritonavir/ombitasvir + dasabuvir is considered one of the most effective and well-tolerated regimens used to treat chronic hepatitis C, with response rates over 95%. Ease of administration, excellent tolerance, and the absence of severe side effects have made treatment of chronic hepatitis C possible even in patients with severe fibrosis and in those with comorbidities. Insomnia, headache and fatigue are the most commonly reported side effects, the serious adverse events being uncommon. We will report a case of stroke as a possible serious adverse effect during treatment with paritaprevir/ritonavir/ombitasvir + dasabuvir (PrOD) in a 61-year-old male, former smoker, without cardiovascular history, in whom a conflict situation resulted in a hypertensive episode accompanied by paresthesia in the upper and lower right limbs, vertigo, equilibrium disorder, which turned out to be a stroke. **Conclusions**: Because the reported case may be a rare serious effect during the treatment with parita previr/ritonavir/ombitasvir + dasabuvir in a patient with hepatitis C virus (HCV) cirrhosis and without a cardiovascular history, careful neurological monitoring is recommended during this therapeutic regimen. **Keywords**: PARITAPREVIR, RITONAVIR, OMBITASVIR, DASABUVIR, STROKE, CHRONIC HEPATITIS C.

Current treatment of hepatitis C virus infection is based on various oral regimens with direct-acting antiviral agents (DAAs) that have high rates of sustained virologic response (SVR), very good tolerability, low rates of serious adverse events or treatment discontinuation, and require a shorter treatment duration than interferon and ribavirin therapy (1).

New recommendations for the treatment of HCV infection consist of drug combinations and therefore efficacy and safety are assessed especially in patients using combination therapy, making the obtained data difficult to interpret for only one drug (2).

Paritaprevir/ritonavir/ombitasvir + da-

sabuvir stops HCV multiplication and infection of new liver cells. Ombitasvir and paritaprevir block two proteins essential for virus multiplication. Ritonavir acts as a potentiator and prolongs the action of paritaprevir in the body. Dasabuvir (250 mg) stops viral multiplication and infection of new liver cells.

Both paritaprevir/ritonavir/ombitasvir and dasabuvir are pan genotypic DAAs and are administered according to a protocol for 3 months in viral hepatitis C patients with or without cirrhosis (1, 3).

The most common side effects of these combined therapies are: insomnia (30%), headache (24%), and fatigue (20%). The serious adverse events have been reported during or after the treatment (4, 5).

We present a case of stroke as a severe and rare adverse event in a 61-year-old patient. Data related to the history of the disease, laboratory examinations, investigations and monitoring are presented. The patient has consented to the use of the data for scientific purposes.

CASE REPORT

A 61-year-old male patient, Caucasian, retreated, without significant heredocolateral history, residing in an urban area was diagnosed with chronic HCV infection in 2005. He received treatment with peginterferon α-2a + ribavirin for 4 months in 2006, being declared non-responder. He presented to the Iasi Clinic of Infectious Diseases in June 2017 for clinical and biological evaluation and investigations aimed to assess the opportunity of PrOD therapy.

The patient said he quit smoking 2 years ago and had no personal or family history of disease.

He had no specific complaints except fatigue. Physical examination revealed a mild hepatomegaly (about 3 cm below the costal margin) and normal blood pressure. Laboratory investigations at the initiation of therapy revealed AcHCV - present, viral load (HCV RNA) - 1690,000 IU/mL, FIBROMAX-F4 A3 S1 N1 H0, leukocytes = 9370/mm^3, hemoglobin = 18.6 g/dL, GGT = 91 IU/l, INR 1.53, ALAT = 53 IU/L, ASAT = 54 IU/L, bilirubin = 0.87 mg%, cholesterol = 153 mg%, serum albumin = 4.83 g/dL, AFP = 3.80 IU/l (N <5).

Abdominal ultrasound: no ultrasound suspected macronodules, calcification of 8 mm in segment VII, subcapsular, absence of ascites.

Cardiology consultation revealed arterial pressure (AP) 120/70 mmHg, electrocardiogram - sinus rhythm, 86 beats/min, no ischemic changes. The diagnosis at the initiation of antiviral therapy was compensated HCV LIVER CIRRHOSIS, Child score 5A.

In September 2017, PrOD therapy was initiated, at which time the liver function tests revealed ALAT 85 IU/L, ASAT 83 IU/L, total bilirubin 1.25 mg/dL.

Three weeks after the initiation of the therapy he experienced right hemi body paresthesia, vertigo, balance disorder, accompanied by a hypertension crisis (AP = 200/100 mmHg), for which he presented to the Focsani Hospital. Following the consultation, he was sent home with a decreased value of AP (170/80 mmHg), but he didn't mentioned a medication to be continued in ambulatory.

After 4 weeks of treatment the patient presented for a check-up and in view of obtaining the second prescription of the recommended medication, when it was found that the therapy was well tolerated, liver function tests returned to normal (ALAT = 27 IU/mL, ASAT = 33 IU/mL, total bilirubin = 0.7 mg/dL), and physical examination and blood pressure were with-

in normal range. He didn't declared the previous episode of hypertension.

After 5 weeks of treatment with PrOD, the patient presented to the "Prof. Dr. N. Oblu" Emergency Clinical Hospital from Iasi with the same manifestations as those experienced during the previous episode; he was admitted for 5 days, period during which DAA treatment was discontinued. The native cerebral computed tomography (CT) scan was normal, and the psychological consultation indicated an anxiety-depressive syndrome for which psychiatric consultation was recommended.

The diagnosis at discharge from the "Prof. Dr. N. Oblu" Emergency Clinical Hospital from Iasi was: left hemiparesis, minor recurrent ischemic accidents in the right carotid system, anxiety-depressive syndrome, HCV cirrhosis. Anticoagulation/antiplatelet treatment, Holter EKG monitoring, contrast enhanced cranio-cerebral magnetic resonance imaging (MRI) and follow-up visit one month after discharge were recommended.

The psychiatric consultation before the discharge from the neurology hospital made a diagnosis of severe depressive disorder and treatment with bromazepam and tianeptine sodium was recommended.

The patient returned to the Clinic of Infectious Diseases in good general state, with no neurological disturbances (motor deficit, speech disorders). Giving the fact that the first treatment was not completed (the length of the treatment should be 12 weeks and he only had 4 weeks), at his insistent request, PrOD therapy was resumed, in order to achieve a sustained virological response. Holter ECG monitoring was performed and it did not reveal changes in heart rate, and blood pressure levels within normal range.

Three days after the resumption of DAA therapy, unsystematic muscle contractions (upper and lower limbs) and cutaneous hyperesthesia occurred. Viral load (HCV RNA) was undetectable and the liver function tests were normal.

The next day, the general state of the patient had worsened: motor deficit in the right hemi body and speech disorders. The permanent discontinuation of PrOD therapy was decided, and the patient was referred for neurological reassessment, a diagnosis of right hemiplegia and stroke in the left superficial sylvian territory being made. After 6 months of rehabilitation therapy, the patient could rise to an erect position and walk possible intermittent spastic on the right side, right hemiparetic motor deficit, predominantly brachial, normal deep tendon reflexes in the upper and lower right limbs, but viral load (HCV RNA) became detectable, and ALT and ASAT levels remained normal.

DISCUSSION

Stroke occurred in a 61-year-old patient with advanced compensated liver disease (HCV liver cirrhosis) without a cardiovascular history, former smoker, on the 5th week of treatment with paritaprevir/ ritonavir/ombitasvir + dasabuvir. Worth mentioning is the early response to antiviral therapy (undetectable viral load at 4 weeks), but with a documented relapse 6 months after discontinuation of the therapy administered for 6 weeks. This is the only case that developed a severe cerebrovascular adverse effect of the 680 PrOD-treated patients in the Iasi Hospital for Infectious Diseases between 2016 and June 2018. Though, it should be mentioned that is possible that the stroke could have been an independent event, with no connection to the oral antiviral treatment.

In the literature (4, 6), serious adverse

events reported during treatment included isolated episodes: stroke, myocardial infarction, liver decompensation, acute kidney failure due to dehydration, anxiety, aggravation of psoriasis, hypokalemia, gastroenteritis, colitis.

In an analysis (7) of direct-acting antivirals (DAAs) for chronic hepatitis C conducted in 2017 by the Cochrane Hepatobiliary group (including 138 trials randomizing a total of 25,232 participants), 5 cases of severe cerebrovascular adverse events (stroke, cerebral ischemia, cerebrovascular accident) were recorded.

In a large cohort of 1008 patients with HCV genotype 1b compensated cirrhosis treated with PrOD + ribavirin for 12 weeks, Trifan *et al.* (8) reported only 1 case of stroke in the group of patients aged over 70, which required treatment discontinuation. Recently, Kaneko (5) reported severe cerebrovascular adverse events (including subarachnoid hemorrhage and cerebral hemorrhage) in 2 patients receiving Sofosbuvir- ledipasvir and Zaid (4) in one patient during combined sofosbuvir- daclatasvir therapy. More importantly, treatment discontinuation was very infrequent, even in large cohort of DAA therapy in solid organ transplant recipients highlighting the marked improvement in treatment tolerability in an interferon-free era (9).

Among HCV-infected subjects, the presence of steatosis was found to be an independent risk factor for carotid atherosclerosis and subsequently chronic HCV infection increases the stroke risk and should be also considered an important and independent risk factor (10). Our patient had a low degree of steatosis (S1) in the absence of a metabolic syndrome (serum cholesterol, normal blood glucose level), or a medication predisposing to drug interactions.

Reoccurrence of neurologic phenomena upon resuming antiviral therapy and their degree of severity during the second episode allows us to claim that PrOD therapy and the neurologic event are very likely connected.

From what we know up to now by studying the literature, no direct mechanism to explain stroke after therapy with DAAs was found (5), these being considered effective and safe, associated with a reduced number of serious adverse effects requiring therapy discontinuation.

CONCLUSIONS

Unexplained ischemic strokes may be considered serious adverse effects of antiviral therapy with DAAs, even in the absence of risk factors. As a result, careful neurological monitoring is recommended for HCV infected patients during treatment with this antiviral regimen or after discontinuation of therapy.

The presented case stands to highlight the possible occurrence of severe repetitive cerebrovascular events, during therapy with PrOD +/- ribavirin, events which require immediate discontinuation of treatment.

Antiviral treatment of advanced hepatitis C should no longer be necessary, HCV-infected individuals should be treated successfully before developing advanced fibrosis or cirrhosis.

NEWS

CIPROFLOXACIN - ALLY OR ENEMY?

Aortic dissection is the most common fatal disease process of the aorta and is precede in most cases by the aneurysm formation. Ciprofloxacin is one of the most often used antibiotic and it is prescribed to treat a broad spectrum of bacterial infections, including infected aortic aneurysm. Results of recent clinical studies revealed that treatment with fluoroquinolone is associated with an increased risk of acute aortic events. In a recent study, Le Maire *et al.*, have induced a sporadic aneurysm formation in mice with high-fat diet and low-dose angiotensin infusion, the effects of ciprofloxacin on smooth muscle cells and frequency of acute aortic events were studied. The results were stunning, incidence of aortic dissection and rupture was almost 10 times higher in the group with ciprofloxacin and this outcome was linked to the increased level and activity of matrix metalloproteinase. Thus, this drug should be used with caution in patients with aortic dilatation and those at high risk for acute aortic events (Scott A. Le Maire, Lin Zhang, Wei Luo *et al*. Effect of Ciprofloxacin on Susceptibility to Aortic Dissection and Rupture in Mice. *JAMA Surg*. doi:10.1001/ jamasurg. 2018.1804).

EPIDEMIOLOGICAL DATA ON SHOCK IN Forensic MEDICINE (Abstract): The shock is a relative frequent diagnostic in forensic medicine. **Material and method**: We realized a statistical study, using 323 deaths through diverse shock typology, registered within the Forensic Medicine Institute of Iaşi in 2000-2009. The concerned variables were: the spread of cases on years, the clinical forms, age, sex, provenience environment, volemic feature, the survival time from the shock to the death, the spread of complications on the form of the shock and survival, the juridical way of death. Our data were introduced in the EXCEL database and statisticaly analyzed by SPSS program. **Results**: We obtained statistic data on shock typology, based on the survival time and based on the complications of shock types. **Conclusion**: Relevant statistic data were obtained on the relations between the factors that generated the shock, the complications induced and the shock types, related also to the juridical way of death.
Key words: SHOCK, EPIDEMIOLOGY, LEGAL MEDICINE, JURIDICAL IMPLICATIONS

Şocul poate fi definit ca un sindrom plurietiologic evolutiv, caracterizat printr-o tulburare hemodinamică gravă, cu hipoperfuzie tisulară, datorită reducerii volumului sanguin sau debitului cardiac, ceea ce conduce la un volum sanguin circulator efectiv inadecvat. Modificările care se succed în etapele patogenezei şocului pot fi reversibile, iar dacă factorii etiologici persistă acestea devin ireversibile cu moartea celulară consecutivă. Afectarea unui număr crescut de celule din organele vitale determină decesul individului chiar în condiţiile eliminării cauzei (1,2,3).

În cazuistica medico-legală, şocul este un diagnostic relativ frecvent ceea ce impune o definire exactă a tipului de şoc, stabilirea condiţiilor de apariţie şi derularea proceselor patologice care au condus la deces. Majoritatea studiilor din literatură cu privire la epidemiologia şocului au la bază diferite studii clinice din serviciile de medicină de urgenţă si terapie intensivă, în care poziţia principală o ocupă şocul septic (4,5). In Anglia 0,003% din totalul consulturilor spitalicesti sunt pentru soc, 72% din cazuri au fost spitalizate, numarul mediu de zile de spitalizare a acestora a fost 6,7 (Hospital Episode Statistics, Department of Health, England, 2002-2003).

Aducerea de date noi legate de acest subiect din cazuistica medico-legală este în opinia noastră o încercare dificilă prin faptul ca nu poate include toate cazurile de şoc, mai ales pe cele de şoc septic, care intră de obicei în cazuistica anatomoclinică.

În studiul de faţă am urmărit corelarea datelor privind factorii care au determinat decesul, complicaţiile apărute şi tipurile de şoc în relaţie şi cu forma juridică de moarte.

MATERIAL ŞI METODĂ

S-au luat în studiu un număr de 323 cazuri de deces prin şoc dintr-un număr total de 9489 autopsii efectuate la Institutul de Medicină Legală Iaşi, pe o perioadă de 10 ani între 2000-2009. S-a efectuat un studiu statistic privind repartiţia cazurilor pe ani, pe vârstă, pe sex şi formă clinică. S-au analizat timpii de supravieţuire în funcţie de tipul de şoc, global şi pe fiecare tip în parte. S-a efectuat o analiză statistică privind distribuţia complicaţiilor pe forme de şoc si supravieţuire. Datele obţinute au fost centralizate în baze de date EXCEL şi SPSS şi prelucrate cu funcţii statistice adecvate.

REZULTATE

În perioada analizată între 2000-2009, la Institutul de Medicină Legală Iaşi s-au efectuat un număr total de 9489 autopsii, iar dintre acestea 323 au fost cazuri de şoc care au reprezentat un procent de 3,4 % din totalul autopsiilor. În anul 2000 au fost înregistrate 905 cazuri din care 28 cazuri cu şoc, în 2001 - 877 cazuri din care 33 cazuri de şoc, în 2002 - 1027 cazuri, din care 34 cazuri de şoc, în 2003 - 918 cazuri din care 30 cazuri de şoc, în 2004 - 865 cazuri din care 34 cazuri de şoc, în 2005 - 874 din care 37 cazuri de şoc, în 2006 - 935 cazuri din care 34 cazuri de şoc, în 2007 - 898 din care 30 cazuri de şoc, în 2008 - 1072 din care 32 cazuri de şoc şi în 2009 - 1018 din care 31 cazuri de şoc.

Distribuţia cazurilor de şoc, pe ani de studiu, a fost bimodală, cu vârfuri de frec-

TABELUL II
Repartiţia cazurilor în funcţie de vârstă şi ponderea procentuală

Vârstă (ani)	Nr. cazuri	Procent
0-10	40	12,3%
10-20	27	8,35%
20-40	89	27,5%
40-60	110	34%
60-80	57	17,64%

venţă în anii 2002 (34 cazuri) şi 2005 (37 cazuri), observându-se o tendinţă uşor crescătoare ($y = 31,8 + 0,0909 x$)(fig.1).

Din numărul total de 323 decese prin şoc s-au evidenţiat următoarele formele clinice de şoc : toxico-septic - 95 cazuri, şoc mixt - 57 cazuri, şoc traumatic 32 cazuri, şoc hemoragic - 47 cazuri, şoc combustional - 72 cazuri, şoc cardiogen - 20 cazuri (tab. I).

În funcţie de vârstă s-au luat în considerare următoarele grupe : 0-10 ani - 40 cazuri, 10-20 ani - 27 cazuri, 20-40 ani - 89 cazuri , 40-60 ani - 110 cazuri, 60-80 ani - 57 cazuri (tab. II).

În funcţie de sex, cazurile au prezentat următoarea distribuţie : la sexul masculin 221 cazuri (68%), iar la sexul feminin 102 cazuri (32%)(tab. III).

În ceea ce priveşte mediul de proveniență, din cele 323 cazuri 214 au fost din mediul rural şi 109 din mediul urban (tab.IV).

În funcţie de componenta volemică, din numărul total de cazuri de şoc au fost 208 cazuri de şoc hipovolemic şi 115 cazuri cu şoc normovolemic (tab.V).

Timpul de supravieţuire de la momentul instalării şocului până la deces a conturat următoarele situaţii : supravieţuire până la 1 oră - 60 cazuri, supravieţuire până la 24 ore - 110 cazuri, supravieţuire între 1-3 zile 57 cazuri, supravieţuire între 3-10 zile 52 cazuri, supravieţuire între 10-20 zile 29 cazuri, supravieţuire între 20-60 zile 15 cazuri.

TABELUL III
Repartiţia cazurilor în funcţie de sex

Sexul	Nr. cazuri	Procent
M	221	68,4%
F	102	21,6%

S-au analizat timpii de supravieţuire în funcţie de tipul de şoc, global şi pe fiecare tip în parte (tab. VI, fig.2).

Pe tipuri de şoc, în funcţie de timpul de supravieţuire se remarcă puternice diferenţe semnificative :

- cel mai frecvent pacienţii cu şoc hemoragic sau mixt au decedat în primele 24 ore în comparaţie cu celelalte tipuri de şoc ;
- pacienţii cu şoc combustional prezintă letalitatea maximă în primele 3 zile ;
- pacienţii cu şoc toxicoseptic prezintă letalitatea maximă în primele 10 zile.

S-a analizat existenţa unei corelaţii statistic semnificative între fiecare tip de complicaţie apărută şi fiecare tip de şoc precum şi între complicaţie şi şoc în general (tab. VII, fig.3).

Din punct de vedere statistic, pe tipuri de şoc, în funcţie de afectare se remarcă :

- ponderea semnificativ mai mare a cazurilor cu afectare MSOF în cazul şocului toxicoseptic, mixt sau traumatic ($p = 0,00005$) ;
- ponderea cazurilor cu afectare renală a fost semnificativ mai crescută în cazul şocului hemoragic sau combustional ($p = 0,000006$) ;
- distribuţia cazurilor cu şoc cardiogen a fost semnificativ mai crescută la pacienţii cu afectare cardiacă ($p < 0,001$) ;

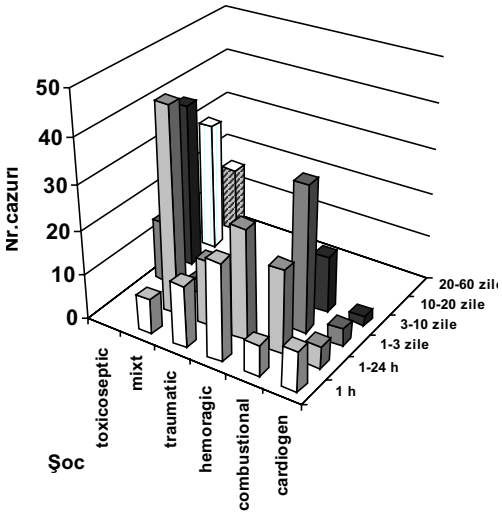

Fig. 2. Distribuţia cazurilor de şoc în funcţie de timpul de supravieţuire

- afectarea pulmonară, digestivă, hepatică şi CID, pe tipuri de şoc, prezintă distribuţii fără diferenţe semnificative din punct de vedere statistic.

În cadrul protocolului medico-legal, fiecare caz a fost clasificat în funcţie de forma juridică de moarte. Din cele 323 cazuri de şoc s-a constatat că 221 din cazuri sunt accidente, 60 cazuri au fost catalogate drept crime, iar suicidul s-a înregistrat într-un număr de 42 cazuri.

DISCUŢII

Din studiul de faţă rezultă că din numărul total de autopsii efectuate la IML Iaşi pe o perioadă de 10 ani, 3,4 % din decese au fost cauzate de diverse tipuri de şoc, procentul rezultat fiind în concordanţă cu

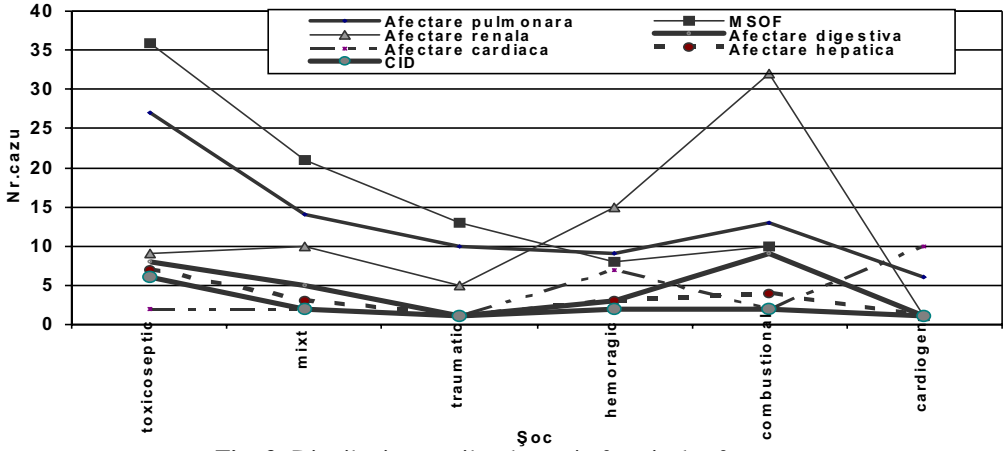

Fig. 3. Distribuţia cazurilor de şoc în funcţie de afectare

datele din literatură. Distribuţia bimodală, obţinută în cadrul studiului nostru, cu vârfuri de frecvenţă în anii 2002 şi 2005, ar putea fi legată de o frecvenţă mai crescută a tipurilor de şoc toxico-septic şi mixt în aceste perioade.

În studiul nostru, cel mai frecvent tip de şoc a fost cel toxico-septic, urmat de cel combustional, însumând peste jumătate din numărul de cazuri. Numeroase studii au demonstrat faptul că sepsisul sever este o cauza principală de deces la pacienţii în stare critică (6,7,8). Cauzele de deces după arsuri severe sunt variabile, însă literatura de specialitate incriminează drept cauză principală insuficienţa multiplă de organ, distribuţia cu exactitate a celorlalte cauze nefiind ştiută (9,10). Grupa de vârstă cea mai afectată de şoc în studiul nostru a fost la adulţii între 40-60 ani, care împreună cu grupa de vârstă 20-40 ani, totalizează aproape 2/3 din cazuri.

S-a constatat că sexul cel mai afectat a fost sexul masculin, în peste 2/3 din totalul cazurilor (11,12). În cadrul repartiţiei pe ani nu s-au observat variaţii semnificative ale prezenţei celor 6 tipuri de şoc. În funcţie de timpul de supravieţuire în funcţie de forma de şoc se remarcă diferenţe statistice puternic semnificative. Cel mai frecvent, decesul la pacienţii cu şoc hemoragic sau mixt s-a produs în primele 24 ore în comparaţie cu celelalte tipuri de şoc, în timp ce la pacienţii cu şoc combustional, vârful de letalitate a fost în primele 3 zile, iar la pacienţii cu şoc toxicoseptic în primele 10 zile (13,14). S-a observat că *perioada de supravieţuire* în cazul a diferite forme de şoc se limitează la maximum 3 zile pentru aproximativ 3/4 din totalul cazurilor, în concordanţă cu literatura şi rapoarte statistice ale departamentelor de sănătate din Anglia şi SUA (15,16).

Analiza statistică privind distribuţia complicaţiilor pe forme de şoc şi supravieţuire a relevat următoarele complicaţii generatoare de deces: insuficienţă multiplă de organ (MSOF), complicaţii pulmonare, complicaţii cardiace şi complicaţii renale, acestea fiind pe primele locuri. Mai rar au fost întâlnite complicaţii digestive, hepatice şi de tip CID (17). *Afectarea organică multiplă*, alături de afectarea pulmonară şi renală, atât ca leziuni iniţiale cât şi drept complicaţii apărute în evoluţie sunt legate de decesul

a 75% din cazuri (18). Cazurile de accident au predominat în cazuistica noastră reprezentând peste 2/3 din numărul deceselor prin şoc.

CONCLUZII

Studiul nostru este printre puţinele studii care realizează o cercetare amănunţită asupra epidemiologiei şocului în cazuistica medico-legală. Am obţinut date semnificative statistic privind relaţiile dintre factorii care au determinat decesul, complicaţiile apărute şi tipurile de şoc.

Ca interpretare medicolegală atrage atenţia faptul că cele mai severe forme de şoc se corelează cu forma juridică de moarte. Exista o corelaţie intre şocul hemoragic şi mixt şi accidentele rutiere.

CLINICAL SIGNIFICANCE OF C-REACTIVE PROTEIN LEVELS IN PREDICTING RESPONSIVENESS TO IRON THERAPY IN PATIENTS WITH INFLAMMATORY BOWEL DISEASE AND IRON DEFICIENCY ANEMIA (Abstract): Iron deficiency anemia (IDA) has been recognized as a major cause of anemia in inflammatory bowel disease (IBD). Anemia has a significant impact on the quality of life of these patients and thus correction is very important. **Aim:** To determine if systemic inflammation (assessed by C-reactive protein [CRP]) can predict the response to iron therapy (oral versus intravenous). **Material and methods:** A seven-month prospective study (June-December 2016) conducted at the Iasi Institute of Gastroenterology and Hepatology. Sixty-three patients with IBD and IDA were assessed. Inflammation was defined as CRP levels > 4mg/L. Patients were divided as follows: 29 patients received iron based oral treatment (group A) and 34 intravenous therapy [IV] (group B). **Results:** Of the 29 group A patients 14 responded (11 had CRP levels < 4mg/L and 3 CRP levels > 4mg/L) and 15 did not respond (3 with CRP levels < 4mg/L and 12 with CRP levels > 4mg/L). As to the 35 group B patients, 25 responded (12 with CRP levels < 4mg/L and 13 with CRP levels > 4mg/L) and 9 did not respond (4 with CRP levels < 4mg/L and 5 with CRP levels > 4mg/L). Among iron tablet-treated patients, hemoglobin (Hb) increase was significantly slower in the high versus low CRP subgroup (2.8 vs 3.8 g/dL, p=0.04). Response to IV therapy was independent of inflammation. **Conclusions:** Patients with higher CRP levels achieved a lower Hb response with oral iron therapy. CRP may be useful in selecting the iron administration route as well as identifying IBD patients who can benefit from first-line IV iron therapy to improve their IDA. **Keywords:** INFLAMMATORY BOWEL DISEASE, IRON DEFICIENCY, ANEMIA, IRON THERAPY, C-REACTIVE PROTEIN.

Inflammatory bowel diseases (IBD) consisting of Crohn's disease (CD) and ulcerative colitis (UC) are conditions of the gastrointestinal tract characterized by peri-

ods of activity and remission, multifactorial etiology and underlying mechanisms that remain incompletely elucidated. Anemia is the most common extraintestinal complication (EIC) in IBD patients (1). Its major importance lies not only in the negative impact on the quality of life (QoL) of these patients, the increased number and duration of hospitalizations and healthcare costs, but also in its continuing underestimation in current clinical practice (2).

In IBD patients, anemia can have a variety of different causes etiologies of which the most important are iron deficiency anemia (IDA) followed by anemia of chronic disease (ACD) (3). For a correct management and approach, it is necessary to distinguish between them as the treatment is different.

IDA is known to be the most common type of anemia in IBD patients. In Romania, the prevalence of the different types of anemia in IBD patients is as follows: 78% - IDA, 15% - mixed anemia and 8.8% - ACD (4).

The main causes of iron deficiency in IBD patients include: chronic intestinal bleeding from inflamed mucosa, inadequate intake during active disease and/or impaired absorption (5, 6).

In IDA, serum ferritin is an indicator of iron storage. A level lower than 15 ng/ml for women or 30 ng/ml for men is characteristic for absolute iron deficiency and in the absence of chronic inflammation associated with low hemoglobin (Hb) for IDA. However, ferritin is also an acute-phase protein and in the presence of chronic inflammatory conditions, such as IBD, its levels may be increased if there is active disease even in patients with IDA (7).

Different biological markers have been used in IBD for various purposes. Of these, we mention C-reactive-protein (CRP), an acute phase protein with pentameric structure, produced by hepatocytes. CRP has been extensively studied over time: from correlating it with endoscopic activity (8, 9, 10), predicting relapse (11, 12), postoperative recurrence (13) and evolutive aspects (14) to predicting response to different treatments (15, 16).

CRP is used to screen for anemia in patients with IBD, along with full blood count and ferritin test, and a level > 5 mg/L is considered significant for systemic inflammation. According to the European Consensus recommendations, it should be measured every 3 months in patients with active disease and at 6, 12 months for those in remission or with mild impairment (3). In the presence of inflammation (CRP > 5 mg/L), ECCO guidelines recognize iron deficiency as a cause for anemia if ferritin level is < 100 ng/dL (17).

Studies have shown that, even when detected, IDA is rarely treated, and that it is usually managed with oral iron supplementation, without regard to other parameters besides Hb and clinical status, although it is known that 90% of the ingested iron remains unabsorbed and that chronic inflammation decreases iron absorption in the gut (18). The goal of treatment, which involves oral or intravenous iron, is to normalize the Hb levels, replenish iron stores and improve QoL (19, 20, 21).

The aim of this study was to determine if systemic inflammation, assessed by CRP, predicts the response to oral versus intravenous iron therapy.

MATERIAL AND METHODS

Between June and December 2016, we performed a prospective analysis of 63 patients with IBD and IDA admitted to the

Iasi Institute of Gastroenterology and Hepatology. Clinical and demographic parameters (age, gender, phenotype, disease duration, extension and activity) were recorded.

Anemia was defined as according to the World Health Organization (WHO): Hb <12 g/dL in women and <13 g/dL in men. The serum markers assessed at baseline were: Hb, erythrocyte indices, ferritin, transferrin saturation (TSAT), iron levels and CRP.

The studied population were patients diagnosed with UC/CD who had IDA (defined as: Hb <12g/dL in women and <13 g/dL in men, TSAT <20% and serum ferritin <100 ng/ml). We followed the recommendations of the European guidelines for the selection of the iron management method. In group A we included patients with mild anemia, inactive disease and who have not had a history of intolerance to iron. Patients with Hb <10g/dL, with active disease and previous intolerance to oral iron route were included in group B.

We divided the patients into two groups as follows: 29 patients were treated with iron-based oral treatment (group A) and 34 with intravenous (IV) therapy (group B). The oral treatment used was ferrous sulfate - 100 mg (FS) administered b.i.d. for 12 weeks and the IV one ferric carboxymaltose (FCM) - maximum 1,000 mg per infusion, weekly, until the patient's calculated cumulative dose had been reached.

Excluded were patients with co-existing causes of anemia: other gastrointestinal causes (hemorrhoids, gastroduodenal ulcers, B12 and folic acid deficiency), myelosuppressive medication (methotrexate and sulfasalazine), renal-urinary and genital causes or pregnancy in women.

Disease activity was determined using Ulcerative Colitis Disease Activity Index - UCDAI for UC and Crohn's Disease Activity Index - CDAI for CD. Inflammation was defined as CRP levels > 5mg/L. Hb level was measured at 4, 8 and 12 weeks. Ferritin and serum iron levels were also reassessed at 12 weeks. Response to treatment was defined as absence of anemia (Hb > 12 g/dL in women and 13 g/dL in men) at 12 weeks and increase in Hb level > 2g/dL at 4 weeks.

The collected data were analyzed using the *SPSS 23.0* software. We used Pearson's Chi-squared test to correlate inflammation at baseline (CRP > 4 mg/L) with response to iron supplementation (defined by the absence of anemia at 12 weeks), oral vs IV administration.

RESULTS

The study population comprised 63 patients with IDA and IBD: 44 with UC and 19 with CD. Demographic parameters were (tab. I): age (mean: 36.72 ± 6.28 years), gender (58.73% men, n=37; sex ratio: 1.42), smoking status (52.38%, n=33 - never smoked).

Duration of disease was 6.24 ± 3.28 years. In terms of disease activity: 33 (52.38%) had mild disease, 25 (39.68%) moderate disease, and severe disease activity in 5 (7.93%) cases.

Of those with CD, 16 (25.3%) had ileal disease, 26 (41.26%) colonic disease and 21 (33.3%) an ileocolonic location. Most of the CD patients had an inflammatory phenotype (73%, n=46), 19% (n=12) a stricturing phenotype and 6% (n=4) a penetrating one. Both, structuring and penetrating phenotypes were encountered in 2% of cases (n=1). On the other hand, 14 (22.2%) of the UC patients had proctitis, 39 (61.9%) left-sided UC and 10 (6.30%) an extensive UC.

TABLE I

Clinical and demographic characteristics of patients with IBD and IDA

	IBD and IDA n (%)	CD n (%)	UC n (%)	p value
Number of Patients	63 (100)	19 (30.16)	44 (69.84)	0.001
Men/Women	37 (58.7)/26 (41.2)	8 (42.10)/11 (57.89)	29 (65.90)/15 (34.09)	0.018
Mean age (years)	36.72 ± 6.28	31.52 ± 2.78	39.15 ± 3.84	0.002
Smoker/ Ex-smoker/ Non-smoker	17 (26.98)/13 (20.63)/ 33 (52.38)	8 (42.10)/ 3 (15.78)/ 8 (42.10)	9 (20.45)/ 10 (22.72)/ 25 (56.81)	0.001
Disease activity: mild/moderate/severe	33 (52.38)/ 25 (39.68%)/ 5 (7.93)	9(47.36)/9(47.36)/ 2(10.52)	24 (54.54)/16 (36.36)/ 3 (6.81)	0.073
CD location L1/ L2/ L3/ L4	N/A	16 (25.3)/ 26 (41.26)/ 21 (33.33)	N/A	0.081
CD phenotype B1/ B2/ B3	N/A	46 (73)/12 (19)/ 4 (6.34)	N/A	0.026
UC extension E1/ E2/ E3	N/A	N/A	14 (22.22) / 39(61.9) /10(6.30)	0.031

Mean baseline Hb level was 9.8 g/dL (range 7.5-10.7). In UC patients, anemia was predominantly found in case of extensive disease (39.7%, $p<0.05$) and in CD in patients with penetrating behavior (21.05%, $p<0.01$). Anemia was found more often in patients with severe disease activity (59.32%, $p=0.07$). There was no statistically significant correlation between disease duration and anemia.

Symptoms of anemia (fig.1) were found in 73% of the study patients that consisted in: fatigue (93.4%), reduced physical performance and cognitive function (84.7%), headaches (15.2%) and sleeping disorders (8.6%).

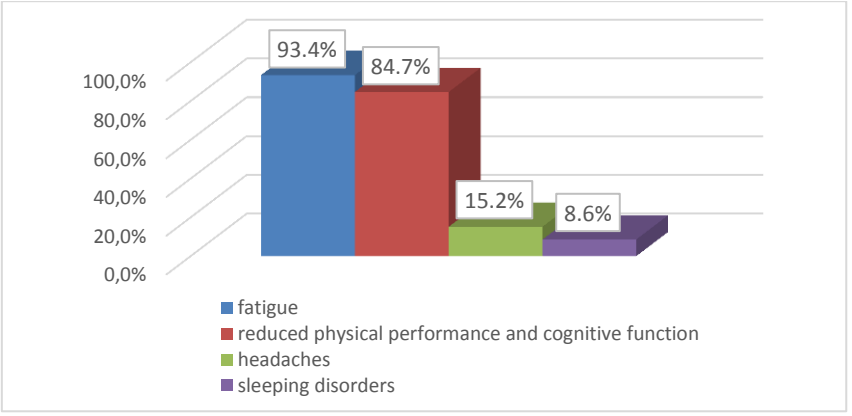

Fig. 1. Symptoms of IDA in the study population

Inflammation was defined as of CRP levels > 5mg/L. Twenty-three patients had 'high CRP levels' while 40 of them had 'low CRP levels' (fig 2.).

In group A (tab. II), Hb level at week 12 increased with: 2.8 ± 0.1 g/dL in those with 'high CRP' and 3.8 ± 0.2 g/dL in those with 'low-CRP'.

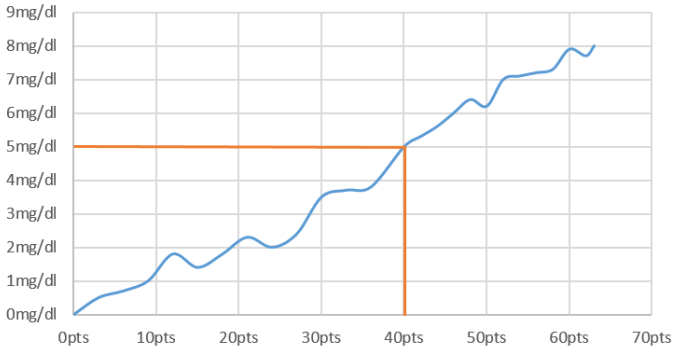

Fig. 2. Distribution of CRP levels (cut-off 5 mg/dL) among study patients

In those receiving IV iron therapy (tab. III), increases at week 12 were: 3.2 ± 0.1 g/dL and 3.6 ± 0.2 g/dL respectively.

Of the 29 group A patients (tab. IV) 14 responded (11 had CRP < 4mg/L and 3 CRP > 4mg/L) and 15 did not respond (3 with CRP < 4mg/L and 12 with CRP levels > 4mg/L).

As to the group B patients (tab. V), 25 responded (12 with CRP < 4mg/L and 13 with CRP > 4mg/L) and 9 did not respond (4 with CRP < 4mg/L and 5 with CRP > 4mg/L).

TABLE II

Increase in Hb levels (g/dL) in patients treated with oral iron

	Oral iron therapy		
	CRP > 4 mg/dL	CRP < 4 mg/dL	p value
Hb (g/dL) week 4 ± SD	1.9 ± 0.2	2.8 ± 0.2	0.001
Hb (g/dL) week 8 ± SD	2.6 ± 0.3	3.6 ± 0.3	0.029
Hb (g/dL) week 12 ± SD	2.8 ± 0.1	3.8 ± 0.2	0.043

TABLE III

Increase in Hb (g/dL) levels in patients treated with intravenous iron

	IV iron therapy			
	CRP > 4 mg/dL	CRP < 4 mg/dL	p value	
Hb (g/dL) week 4 ± SD	2.6 ± 0.2	2.8 ± 0.2	0.036	
Hb (g/dL) week 8 ± SD	2.9 ± 0.3	3.8 ± 0.3	0.048	
Hb (g/dL) week 12 ± SD	3.2 ±0.1	3.6 ± 0.2	0.001	

TABLE IV

The correlation between the response to oral iron treatment and CRP values

Iron based oral treatment		
Treatment response	Number of patients	CRP value
Positive	11	<4mg/L
	3	>4mg/L
Negative	3	<4mg/L
	12	>4mg/L

TABLE V

Correlation between intravenous iron response and CRP levels

IV iron therapy		
Treatment response	Number of patients	CRP value
Positive	22	<4mg/L
	3	>4mg/L
Negative	4	<4mg/L
	5	>4mg/L

Among iron tablet-treated patients, the mean Hb increase was significantly slower in the 'high' versus 'low' CRP subgroups (2.8 vs 3.8 g/dL, p=0.04). Response to IV therapy was independent of inflammation.

In our patients no SAEs were seen; gastrointestinal side effects were more frequent in group A vs. group B (vomiting: 3% vs 1.2%, diarrhea: 2.8% vs. 0.7% and nausea 2.6% vs. 0.8%) but there were no symptoms requiring discontinuation of treatment.

DISCUSSION

Although conducted on a relatively small number of patients, our study presents data consistent with those reported in the literature. As shown by Gasche *et al*. (22), Iqbal *et al*. (23), CRP is useful in selecting the iron treatment method.

In our study, we noticed that in patients treated with oral iron the response to treatment was in accordance with the baseline CRP level. In this group, increases in Hb levels were more significant in those with CRP < 4 mg/dL (week 4: 2.8 vs. 1.8 g/dL, week 8: 3.6 vs. 2.6 g/dL and week 12: 3.8 vs 2.8 g/dL, p=0.04).

It was noted, according to the increase in Hb levels, that irrespective of the form of administered iron, the results are relatively similar when the endpoint has been reached (week 12).

As well as in the study published by Schroder O. (24), in the IV group we noticed the lack of correlation between CRP level and Hb increase, suggesting no link with the degree of inflammation (week 12: 3.2 vs. 3.6 g/dL, p<0.001).

These findings indicate that the best choice in patients with IBD, IDA and elevated baseline CRP is intravenous iron.

In terms of adverse effects, as reviewed by a recent meta-analysis (25), the likelihood of severe adverse effects (SAEs) is higher in those receiving IV iron therapy while gastrointestinal effects are more commonly reported in those receiving oral treatment, which has also been seen in our patients.

CONCLUSIONS

Our study, through the above mentioned, contributes to the establishment of the right therapeutic strategy in patients with IBD and IDA. CRP, as an indicator of inflammation, predicts by its level (high or low) the response to iron treatment. Therefore, it may be considered a useful tool in selecting the most efficient method of iron administration and also in selecting the patients that can benefit from IV iron as first-line therapy.

2. Institutul de Sănătate Publică Iaşi

p-ANCA PREVALENCE IN ULCERATIVE COLITIS PATIENTS AND FIRST-DEGREE RELATIVES (Abstract): Perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA) are more common in patients with ulcerative colitis (UC) than in patients with Crohn's disease (CD), but its prevalence depends on the population being studied and the method employed for its detection. **Aim**: To determinate the prevalence of p-ANCA in ulcerative colitis (UC) patients and their first degree in NE Romania area. **Material and method**: In this study, we investigated the prevalence of p-ANCA as detected by ELISA, in the serum of 44 patients with UC and 22 first degree relatives. We also correlated the presence of this antibody with disease activity and extent, extraintestinal complications and therapy. 26 healthy individuals comprised the control group. **Results**: p-ANCA was detected in 11% of the patients with UC. Of the 5 p-ANCA positive UC patients, 1 case were found to have proctosigmoiditis, 1 cases had left-sided colitis and 3 cases had pancolitis. There was no correlation between the presence of this antibody and any of the studied clinical variables (extend disease, complication, family disease, surgery). No person of the first degree and control group presented positive test. **Conclusions**: The prevalence of p-ANCA in NE Romania patients with UC (11 %) is lower than that in the Western population. The negativity of p-ANCA in all first degree relatives of NE Romania UC patients should be further elucidated. **Key words**: pANCA, ULCERATIVE COLITIS, ELISA

Diagnosticul serologic din rectocolită ulcerohemoragică (RCUH) cuprinde o serie de anticorpi cu importanţă diferită în precizarea diagnosticului. Printre aceştia se numără şi anticorpii anticitoplasmă neutrofilică ANCA care au fost descoperiţi de mulţi ani ca markeri ai dezechilibrului imunologic în boala inflamatorie intestinală (BII), patternul pANCA - perinuclear ANCA fiind mai specifici pentru RCUH (1). Anticorpii ANCA reprezintă o familie de autoanticorpi din clasa imunoglobulinelor G şi M îndreptaţi împotriva unor antigene ţintă reprezentate de ganulaţiile azurofile ale polimorfonuclearelor (proteinaza 3 şi mieloperoxidaza). Determinarea acestor anticorpi se face prin imunofluorescenţă, sau, cu acurateţe sporită prin ELISA.

Utilitatea determinării ac pANCA este motivată din mai multe considerente:

- ca test adjuvant în precizarea fenotipului de BII (RCUH sau Boală Crohn),
- markeri pentru evoluţia bolii şi precizarea tratamentului.

Scopul acestui studiu a fost de a evalua semnificaţia seroprevalenţei anticorpilor pANCA la pacienţii cu RCUH din N-E României şi rudele lor de gradul I.

MATERIAL ŞI METODĂ

În studiu au fost incluşi pacienţi diagnosticaţi cu RCUH în Institutul de Gastroenterologie şi Hepatologie Iaşi şi rudele lor de gradul I. S-a constituit în acelaşi timp şi un lot martor din 26 subiecţi sănătoşi, comparabil ca distribuţie pe grupe de vârstă şi sex cu loturile studiate.

Pacienţii evaluaţi au fost grupaţi în 3 categorii :

- *grupul cu RCUH* include 44 pacienţi diagnosticaţi cu RCUH ;
- *grupul rudelor de grad I* al pacienţilor cu RCUH, 22 persoane ;
- *grupul de control* include 26 subiecţi sănătoşi cu distribuţie pe grupe de vârstă şi sex similară cu a pacienţilor din lotul de studiu.

Includerea pacienţilor în studiu s-a bazat pe următoarele criterii :

- *criterii diagnostice* definite pe baza datelor clinice, endoscopice, histologice, radiologice ;
- *criterii evolutive* - boală cu o durată de cel puţin 2 ani.

Severitatea bolii a fost apreciată în raport cu criteriile Truelove şi Witts cu definirea formelor uşoare, moderate şi severe de boală.

Evaluarea extinderii leziunilor inflamatorii s-a făcut prin examinare endoscopică cu încadrare în proctită (afectare rectală), colită stângă (afectare până la unghiul splenic al colonului), pancolită (afectare colonică întinsă ce depăşeşte unghiul splenic al colonului).

Criterii de excludere au fost pentru pacienţii care au primit terapie imunosupresivă considerată ca medicaţia susceptibilă de a modifica titrul ac pANCA, aspect care este însă controversat (2).

Din probele de sânge recoltate s-au efectuat testări serologice pentru evidenţierea pANCA, utilizându-se pentru determinare metoda ELISA.

Metoda de determinare

Pentru determinarea pANCA a fost utilizată metoda cantitativa ELISA, cu evidenţierea mieloperoxidazei (MPO) şi proteinaza 3 (PR3) ca antigenelor responsabile pentru pANCA. Metoda are la bază o reacţie indirectă cu fază solidă de tip sandwich, cu realizarea în ser a unui complex antigen--anticorp între enzimele IgG conjugate cu MPO PR3. Testările serologice s-au efectuat în cadrul Laboratorului de Microbiologie, Institutul de Sănătate Publică Iaşi (laborator autorizat în efectuarea testelor ELISA), cu analizor automat pentru ELISA, ETI-STAR, (DiaSorin Italia). Fiecare probă biologică reprezentată de serul provenit de la subiecţii incluşi în studiu a fost prelucrată în acord cu instrucţiunile specificate pentru metoda de determinare. Procedura de lucru presupune mai multe etape :

1. Se prepară tamponul de spălare şi diluentul pentru probe.
2. Se diluează probele. Probele de ser sau plasmă se diluează 1 : 100 cu diluant pentru probe (10 μL ser sau plasma + 990 μL diluant)
3. Se marchează pe foaia de lucru poziţia probelor în godeuri incluzând 6 godeuri pentru calibratori, 2 pentru Controalele Pozitive (PC) şi două pentru Controalele Negative (NC). Se poate opta şi pentru testarea probelor în duplicate.
4. Se aşează în holder numărul necesar de godeuri.
5. Se pipetează în godeuri câte 100 μL de Calibratori, controale şi probe diluate.
6. Se incubează 30 minute la temperatura camerei.
7. Se spală de 3 ori cu câte 300 μL de tampon de spălare.
8. Se pipetează câte 100 μL de Conjugat în fiecare godeu.
9. Se incubează 15 minute la temperatura camerei.
10. Se spală de trei ori ca în pasul 7.
11. Se pipetează în fiecare godeu câte 100

TABELUL I
Valori pANCA prin testare ELISA

Interpretare	Ac anti-PR3 (U/mL)	Ac anti-MPO (U/mL)
Normal	<5	<5
Crescut	>5	>5

µL de Substrat pastrând aceeaşi ordine în care s-a pipetat Conjugatul.

12. Se incubează 15 minute la temperatura camerei.
13. Se adaugă câte 100 µL de reactiv de stopare in aceeaşi ordine ca şi Substratul. Se aşteaptă 5 minute.
14. Se citeşte absorbanta fiecărui godeu la 450 nm dacă se foloseşte un singur filtru, sau la 450/ 600-690 nm dacă se foloseşte un cititor cu două filtre. Reacţia este stabilă pentru cel puţin 30 minute. Citirea densităţii optice trebuie făcută în acest interval de timp.

Valori probabile (aşteptate) sunt redate în tabelul I, cu recomandarea ca fiecare laborator să stabilească propriile limite pentru valorile normale sau patologice.

Evaluarea rezultatelor se face cu ajutorul curbei obţinute. Se recomandă curba cu 4 parametri pentru interpretarea rezultatelor.

Rezultatul pozitiv trebuie raportat la statusul clinic al pacientului. De asemenea, fiecare decizie pentru terapie se stabileşte individual.

Tehnica prezintă o serie de limite legate de calitatea preparării antigenelor, izolarea sau purificarea proteinelor citoplasmatice din neutrofilele umane şi modificările de conformaţie a epitopilor pentru antigen ocupaţi după aderarea la suprafaţă cu antigen.

REZULTATE

Din distribuţia cazurilor referitoare la extensia leziunilor inflamatorii la grupul pacienţilor cu RCUH s-a constatat afectare tip colită stângă în 50% cazuri, pancolită în 32% cazuri şi proctită în 18% cazuri. La acelaşi grup de studiu evaluarea severităţii bolii în raport cu criteriile Truelove şi Witts relevă forme uşoare la 41% pacienţi, forme mederate la 38% pacienţi şi forme severe la 21% pacienţi.

În grupul pacienţilor cu RCUH testul pANCA a fost identificat pozitiv în raport cu valoarea coutoff (> 5U/mL) la 5 pacienţi (11%). Majoritatea titrurilor au fost sub valoare coutoff de 5U/mL. Cel mai mare titru a fost de 17U/mL.

La grupul rudelor cu RCUH şi martori nu s-a înregistrat nici un test pozitiv pentru p ANCA (fig. 1).

Prezentarea pacienţilor cu RCUH şi pANCA pozitiv în raport cu datele demografice, vechimea bolii, extinderea leziunilor, stadiul de activitate este redat în tabelul II.

DISCUŢII

pANCA este raportată în literatură cu o prevalenţă variabilă la pacienţii cu BII. Pacienţii cu RCUH prezintă mai frecvent pANCA (între 33%-84%) comparativ cu boala Crohn (BC) unde pANCA apare la 15% din pacienţi şi caracterizează subgrupul de BC colonică (3,4). În studiul nostru prevalenţa pANCA

TABELUL II
Pacienţii cu RCUH şi pANCA pozitiv

Pacient	Sex	Vârstă	Vechimea bolii	Extensie	Severitate	Complicaţii, ME, chirurgie
1	M	46	3	Pancolită	S	Spondilită anchilozantă, colectomie, pouchită
2	F	25	5	Pancolită	S	Tromboflebită, anemie, megacolon toxic
3	F	34	2	Pancolită	M	CS
4	M	70	10	Colită stângă	M	Pseudopolipi

Legendă S=sever, M=mediu, CS=colangită sclerozantă, ME=manifestări extraintestinale

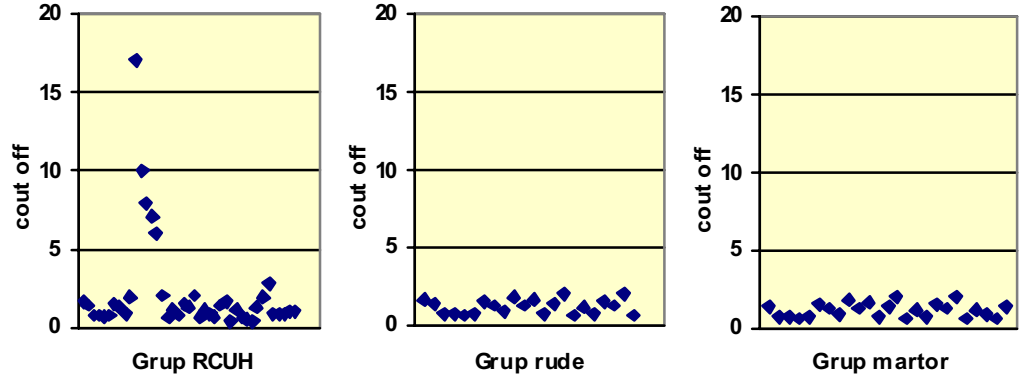

Fig. 1. Rezultate la testul pANCA în loturile de studiu

la pacienţii cu RCUH este mai mică comparativ cu rezultatele raportate de alţi autori. Din totalul pacienţilor testaţi doar 5/44 seruri (11%) au fost pozitive pentru pANCA aparţinând pacienţilor cu RCUH; pacienţii incluşi în grupul rudelor şi martori sănătoşi nu au prezentat teste pozitive. Determinările s-au făcut la pacienţii cu evoluţia bolii de peste 2 ani şi fără tratament imunomodulator care să modifice configuraţia bolii.

Diferenţe de prevalenţă a pANCA au fost constatate la mai multe serii de studii derulate în arii geografice diferite; ele pot fi atribuite atât particularităţilor etnice cât şi tehnicii de lucru utilizate. La pacienţii cu RCUH din Estonia (populaţie cu incidenţă mică a BII comparativ cu seriile europene), pANCA a fost detectată în 29/59 (49%) din cazuri cu RCUH, în 4 din 17 cazuri cu BC şi în 4% din 111 cazuri subiecţi sănătoşi în timp ce la populaţia din UK prevalenţa a fost de 42,4% (5). Pentru ambele boli nu se constată corelaţie între prezenţa de pANCA şi durata sau extensia bolii

Prezenţa pANCA cât şi titrul nu se corelează cu extensia bolii, severitatea puseului de activitate şi forma clinico evolutivă (6). Controverse ale relaţiei pANCA- stadiul de activitate al bolii rezultate din datele diferitelor studii, care raportează atât titruri înalte de pANCA la pacienţii cu RCUH activă, cât şi lipsa de corelaţie între statusul pANCA + şi boală activă, par a fi clarificate de datele unui singur studiu de urmărire pe termen lung a prezenţei şi variaţie titrului pANCA, care precizează absenţa corelaţiei între pANCA şi stadiul de activitate al bolii (1,7). Mai mult, posibilitatea de conversie din pANCA negativ în pANCA pozitiv şi viceversa nu se corelează cu activitatea bolii. În studiul nostru 4/5 pacienţii cu seruri pozitive pentru pANCA prezentau boala în stadiul de activitate şi leziuni extinse la nivelul colonului descendent sau pancolită. Având în vedere numărul redus de teste pozitive, rezultatele constatate nu pot fi considerate definitorii pentru corelaţia între pANCA şi boala activă. Cel mai mare titru de anticorpi a fost înregistrat la un pacient cu pancolită care a necesitat colectomie. În acest caz, tirul ridicat de pANCA a probat nu numai relaţia cu boala activă cu leziuni extinse, dar s-a dovedit şi predictiv pentru pouchita apărută la un an după intervenţia chirurgicală, care a necesitat reintervenţie chirurgicală.

Variaţiile de prevalenţă pot fi explicate prin implicarea factorilor tehnici utilizaţi în diferite metode de determinare (ELISA, imunofluorescenţă) (7). Metoda comună de determinare a anticorpilor pANCA este imunofluorescenţa indirectă (IFI), tehnica ELISA fiind mai recent introdusă. Variabilitatea rezultatelor între diferite laboratoare a impus standardizarea metodelor de determinare, în special pentru studiile comparabile. Dife-

renţele de rezultate între studii ar trebui atribuite nu numai metodelor variate de lucru, dar şi opţiunii laboratorul pentru valoarea de cutoff (valoarea prag de detecţie a antigenelor cu semnificaţie patologică), cu recomandarea ca fiecare laborator să stabilească limitele normale şi patologice (8). Încadrarea valorilor pANCA într-un model cantitativ este folosită în evaluarea clinică şi biochimică a pacienţilor cu RCUH, în estimarea corelaţiilor cu factorii de risc şi stabilirea asociaţiilor epidemiologice.

În studiul nostru serurile pANCA pozitive au fost evaluate prin metoda ELISA, tehnica sandwich, cu valoarea coutoff de 5 U/mL. Pozitivitatea pANCA la populaţia de rectocolitici din NE României trebuie interpretată în raport cu structura genetică a pacientului, natura antigenului împotriva căruia se dezvoltă anticorpii, natura florii intestinale a populaţiei din regiune.

Susceptibilitatea pentru BII poate fi influenţată de genele complexului major de histocompatibilitate HLA, implicate în mod regulat în răspunsul imunologic. În mod distinct a fost raportată asocierea antigenelor CMH clasa I şi II cu RCUH, statusul pANCA pozitiv fiind mai frecvent asociat cu HLA DR2 în timp ce pANCA – este asociat cu HLA DR4 (9). Medierea imunologică a fost un obiectiv urmărit în criteriile de includere a pacienţilor, încât cei care au urmat tratament imunomodulator nu au fost selectaţi.

Determinările HLA pentru compatibilitatea transplantului de organ relevă un mozaic genetic, astfel încât, în lipsa unor studii imunogenetice despre structura genetică a pacienţilor cu RCUH, nu pot fi făcute aprecieri care să demonstreze asocierea dintre pANCA şi HLA pentru populaţia de rectocolitici din această regiune a ţării.

Mai mult, din datele din literatura reiese că această asociere pANCA-markerii genetici nu este confirmată la toate populaţiile, ceea ce denotă o dependenţă mare a pozitivităţii testului de structura etnică a populaţiei. Existenţa unor variaţii regionale importante de tipul extremelor de prevalenţă menţionate în unele studii din Germania, pun sub semnul întrebării relaţia pANCA–HLA. De asemenea, este acceptată şi existenţa unor diferenţe între date complete despre structura genetică a populaţie, care nu permit aprecieri ale relaţiei pANCA şi haplotipul pacientului (10).

Creşterea prevalenţei pANCA la rudele pacienţilor cu RCUH, în special probanţii pANCA pozitiv, validată pe mai multe serii de studiu, susţine ipoteza de marker genetic al susceptibilităţii pentru RCUH (11,12).

În studiul nostru din 22 subiecţi testaţi, rude de grad I ale pacienţilor cu RCUH (copii, părinţi), nici un ser nu este pozitiv pentru pANCA (nici pentru rudele pacienţii pANCA pozitiv şi nici pentru rudele pacienţii pANCA negativ), titrurile de anticorpi fiind sub valoarea coutoff de 5U/l. Absenţa markerilor genetici la rudele pacienţilor cu RCUH, sugerează o structură genetică diferită a populaţiei din regiunea de NE a României. Acest aspect poate reprezenta o particularitate regională, a cărei confirmare necesită analiză în cadrul unor studii suplimentare.

Specificitatea pANCA este dată de prezenţa a doua antigene majore proteinaza 3 (PR3) şi mieloperoxidaza (MPO) şi de un set de antigenelor minore reprezentate de : catepsina, elastaza, lactoferina, lizozimul, proteine bacteriane implicate în creşterea a permeabilităţii. În RCUH antigenele majore sunt rar detectate şi la titruri joase, în timp ce antigenele minore sunt mai frecvent descrise (13). În studiul nostru frecvenţa redusă şi titrurile joase ale ac pANCA rezultate prin determinarea ELISA, pot fi datorate specificitatii kiturilor pentru antigenele majore MPO şi PR3. Din grupul antigenelor minore, lactoferina reprezintă antigenul majoritar. Este cunoscut faptul ca lactoferina umană prezintă o secvenţa comună, de 68%, cu lactoferina din laptele de vacă, cu posi-

bilitatea unei reacţii încrucişate între anticorpii umani şi lactoferină (3). Alimentaţia copilului din primul an de viaţă (naturală sau artificială) pe un sistemul imun imatur, poate fi implicată în apariţia de anticorpi împotriva lactoferinii. Istoricul pozitiv de alimentaţie naturală prelungită până la 1 an, constatat la majoritatea pacienţilor cu RCUH, ar putea argumenta prevalenţa pANCA redusă. De asemenea, este cunoscută şi acceptată coexistenţa diferiţilor antigeni în acelaşi ser, dar numai testele cantitative antigen specific pot defini specificitatea antigenică a pacientului cu RCUH, creând şi premizele unei mai bune corelaţii între titru de anticorpi şi activitatea bolii. Faptul că titrul pANCA s-ar putea corela în principal cu antigenele majore, testarea, prin specificitatea kiturilor, nu permite analiza relaţiei între activitatea bolii şi titrul antigenelor specifici populaţiei cu RCUH din NE României al cărui spectru antigenic nu este cunoscut.

Rolul bacteriilor în patogeneza BII este susţinut de rezultatele studiilor experimentale pe modelul animal, dar nici până în prezent nu a fost identificat un germene specific. Alterarea florei intestinale a fost bine demonstrată la pacienţii cu RCUH. Această ipoteză este susţinută de faptul ca modificări ale concentraţiei florei intestinale se asociază cu scăderea potenţialului protectiv al lactobacilului şi bifidobacteriei (14). Modificarea în timp a frecvenţei RCUH poate fi şi consecinţa modificărilor florei intestinale. Faptul că pANCA reacţionează cu antigenele bacteriene vine în sprijinul ipotezei mimetismului antigenic investigat pentru autoanticorpii direct îndreptaţi asupra lactoferinii, care posedă o secvenţă comună cu proteina de şoc microbiană (15). Nu sunt excluse variaţii de microfloră gastrointestinală umană pentru populaţia din NE României, dacă se are în vedere frecvenţa mare a enterocolitei la populaţia pediatrică. În Estonia a fost comparată microflora bacteriană prin coproculturi prelevate de la copii cu vârstă până la 1 an cu cei din Suedia. Cauza diferenţei de microfloră bacteriană cercetată la cele 2 populaţii rămâne necunoscută. Microflora curentă în populaţia din Estonia este similară cu cea din Suedia unde RCUH este mult mai frecventă, diferenţele fiind atribuite implicării altor cauze (16).

Studiul nostru suportă rezultatele şi pentru un caz de RCUH asociat cu colangită sclerozantă, dar titrul nu se corelează cu activitatea sau extensia bolii. Similar cazului cu pouchită, asocierea pANCA-RCUH-CS vine ca o confirmare a implicării factorului imunogenetic în patogeneza bolii.

CONCLUZII

Frecvenţa mică a anticorpii pANCA la pacienţii cu RCUH din NE României le atribuie un rol limitat în diagnosticul serologic al bolii. Din cauza sensibilităţii reduse, determinarea uzuală a ac pANCA nu este utilizată. Testele pozitive influenţează probabilitatea distincţiei între RCUH şi BC. Titrul acestor anticorpi nu se corelează cu activitatea bolii şi pare stabil în timp.

Probabilitatea susceptibilităţii genetice a RCUH, demonstrată prin frecvenţa mare a bolii la rudele de grad I, reprezintă un punct de interes pentru majoritatea cercetătorilor. Predispoziţia genetică a bolii la rudele de gradul I, verificată prin testări serologice imune, nu se confirmă pentru pacienţii din această regiune a ţării, iar rezultatele testărilor pANCA efectuate la pacienţii cu RCUH din N-E României prezintă valori mult mai mici faţă de datele din literatură. Interpretarea conjugată a frecvenţei reduse a BII familiale şi seroprevalenţa ac pANCA relevă aspecte care argumentează constatările noastre. Nici unul dintre pacienţii cu istoric pozitiv pentru BII nu a prezentat pANCA +.

Considerăm aceste aspecte o particularitate regională, care necesită o documentare susţinută şi extinsă la un număr cât mai mare de pacienţi în cadrul unor studii suplimentare.

OUR EXPERIENCE IN THE SURGICAL TREATMENT OF ACETABULAR FRACTURES, USING SPRING PLATE TECHNIQUE (Abstract): Fractures of the posterior wall, with comminution, are often hard to reduce and stabilize due to the small fragments that are involved, so the "spring plate" technique was developed**. Aim:** To show the advantages and the results we obtained in treating the posterior wall fractures using "spring plate" technique. **Materials and methods:** Included in our study was a number of 21 patients with an average age of 42 years, which had fracture of the acetabular posterior wall or acetabular fracture associated with posterior wall fracture. They were treated by open reduction and internal fixation with one or two spring plates and one or two reconstruction plates overlapping them. **Results:** Postoperative X-rays revealed that anatomic reduction was obtained in 15 cases (72%), was acceptable in 3 cases (14%) and imperfect in 3 cases (14%). Clinical outcomes were very good in 16 cases (76%), acceptable in 4 cases (19%) and poor in one case (5%). **Conclusions:** Using spring plate technique in comminuted posterior wall fracture proves to offer a good stability for small fragments, eliminates the risk of articular penetration of the screws and offers the possibility of early recovery. **Keywords:** SPRING PLATE, ACETABULAR FRACTURE, POSTERIOR WALL.

The fractures of the posterior wall of the acetabulum account around 30% of all acetabular fractures (1), but often they are associated with other acetabular fractures. They are produced by high energy trauma (traffic accidents mainly) (2), but also by low energy trauma in obese patients or persons with osteoporosis (3).

By the 1970, the treatment for these fractures was nonsurgical, having relatively good results in 50-60% of cases (3, 4); then, the studies by Matta (2) and Mayo (5) have demonstrated the superiority of surgical treatment of these fractures, with excellent results in 80-90% of cases, even delayed acetabular fractures have better clinical outcomes after surgical treatment (6).

The surgical treatment is indicated in fractures with step-off greater than 2 mm (7) and depends on the size of fracture site and hip stability (8).

In posterior wall fracture with small fragments, anatomic reduction and internal fixation with reconstruction plate or interfragmentary screw can prove to be very difficult (1), associated with an increased

risk of articular penetration of screws, so Mast *et al.* (9) suggests the use of a plate perpendicular on the bone fragments, covered by the reconstruction plate molded along the posterior column of the acetabulum.

The aim of this study was to demonstrate the advantages and our short-term results of treating the posterior wall fractures by using spring plate technique.

MATERIAL AND METHODS

Between January 2015 and December 2017, 45 patients with acetabular posterior wall fractures were admitted and treated surgically in the Orthopedics and Traumatology Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital, Iasi and "Mavromati" County Emergency Hospital, Botosani. Based on the admission criteria (comminuted posterior wall fracture or other acetabular fractures associated with comminuted posterior wall fracture and minimum of one-year follow-up), 21 patients were included in our study.

Distribution by gender showed a higher proportion of male patients (90%), the gender ratio being M/F 9.5/1. Distribution by age group revealed a peak in the age group 30-40 years, the average age was 42 years old (range 19-79 years). The left acetabulum was more often affected: 14 (77%) cases *vs.* right one: 7 (33%) cases. The mechanism of the injury was high velocity trauma in 90% of the cases (car accident in 12 (57%) cases and falls from height in 7 (33%) cases) and only in 2 (10%) cases of low velocity trauma (fall from ground level).

According to Letournel classification, 9 (43%) cases were classified as posterior wall fracture, 9 (43%) cases as transverse+ posterior wall fracture and 3 (15%) cases as both columns with comminuted posterior wall fracture. The associated local injuries were: posterior hip dislocation in 8 (38%) cases, marginal impaction in 4 (19%) cases, intraarticular loose body in 2 (10%) cases and osteochondral femoral head lesion in 4 (19%) cases. 9 cases had sciatic nerve palsy associated.

Emergency reduction and skeletal traction was applied to patients who had hip dislocation. The period from the trauma to the surgery was on average 7 days (3-21 days) depending on the general status of the patient.

Preoperative imaging included anteroposterior X-rays, oblique Judet views (fig. 1) and CT scans of the pelvis (fig. 2). The indication for surgical treatment was given by hip instability, involvement of over 40% of the posterior wall (fig. 2), step-off greater than 2 mm, intraarticular loose body and marginal impaction.

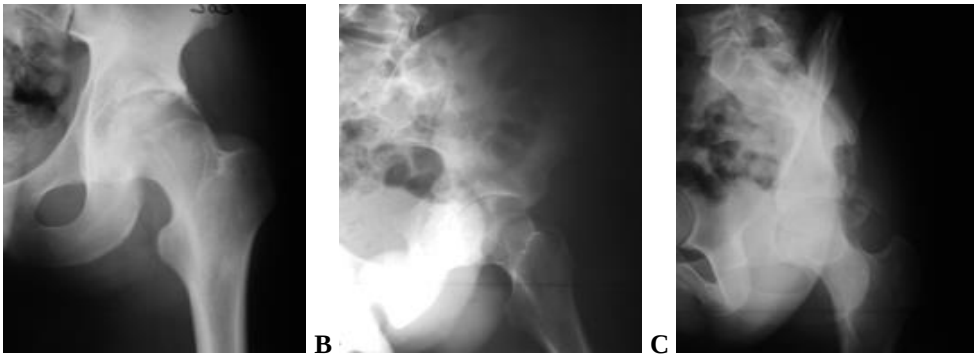

Fig. 1. Hip X-Ray - posterior wall fracture:
AP view **(A),** external oblique view (**B**), internal oblique view (**C**)

For all patients we used a Kocher Langenbeck approach with the patients positioned in prone position in 19 (90%) cases and lateral decubitus in 2 (10%) cases. Open reduction and temporary stabilization of the posterior wall fragments with Kirschner wires was performed. For the definitive internal fixation, we used spring plates made out of one-third tubular plate (fig. 3 A, B) placed with spikes to the border of posterior wall. In 18 (86%) cases we stabilized the plate with an additional screw in the posterior column and in 3 (14%) cases the pressure of the reconstruction plate offered enough stabilization. The number of spring plates used depended on the area and number of fragments that could not be stabilized by other methods, so we used one spring plate in 18 (86%) cases and 2 plates in 3 (14%) cases. The spring plates were overlapped by one preshaped reconstruction plate along the posterior column of the acetabulum in 15 (71%) cases and 2 preshaped reconstruction plate along the posterior column and posterior wall of the acetabulum in 6 (29%) cases. The plates were preshaped on plastic coxal bones (fig. 3 C, D). Intraoperative fluoroscopic images were used to confirm the reduction and position of the plates and screws.

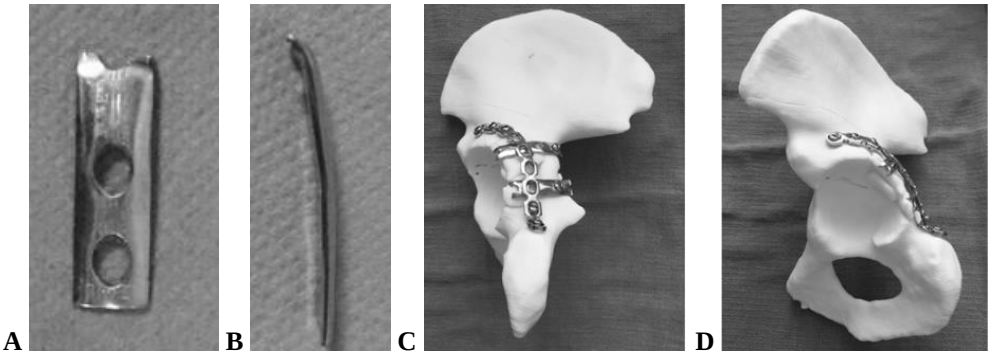

Fig. 3. "Spring plate" made out of one-third tubular plate (photos: **A** - anterior view, **B** - profile); Placement and positioning of the plates on the 3D printed plastic coxal model (photo images: **C** - posterior view, **D** - profile view)

The mean duration of surgery was 2.46 hours (2-4 hours). Blood loss during surgery was on average 500 ml (250-1750 ml). The average duration of postoperative admission was 8 days (4-28 days). Pre- and postoperative prophylaxis of deep vein thrombosis consisted in the administration of low molecular weight heparin, antibiotic prophylaxis was made with III generation cephalosporin, one dose intraoperatively, no prophylactic treatment of heterotopic ossifications was administered.

Follow-up was performed at 45 days, 3, 6 and 12 months. These consisted of physical examination based on the Merle D'Aubigné-Postel score and the radiological findings were graded by Matta criteria (2). Heterotopic ossifications were graded using the Brooker classification (10).

RESULTS

Postoperative X-rays (fig. 4) showed that anatomical reduction was obtained in 15 (72%) cases, was acceptable in 3 (14%) cases and imperfect in 3 (14%) cases. The imperfect results were obtained in the cases of both columns fractures. Clinical outcome was very good in 15 (72%) cases, acceptable in 3 (14%) cases and poor in 3 (14%) cases.

At 45 days follow-up, in one (5%) case we found loss of reduction with subluxation of the hip. Clinically, at 12 months follow-up, walking was completely normal in 14 (67%) cases, a slight limp in 4 (19 %) cases and walking with one crutch in 3 (14%) cases. Hip joint mobility was very good in 14 (67%) cases, good in 4 (19%) cases and poor in 3 (14%) cases. Also, we noticed lack of hip pain in 15 (72%) cases, mild pain in 3 (14%) cases and moderate pain in 3 (14%) cases. Radiologic results at one-year follow-up showed: preservation of initial reduction in 20 (95%) cases; heterotopic ossification Brooker type I in 3 (14%) cases and type II in 1 (5%) case; 2 (10%) cases of hip arthritis; no case of femoral head avascular necrosis.

No case of infection, deep vein thrombosis and non-union was recorded so far. No difference in the surgical result between sexes, the part of injury, age and the position on the surgical table.

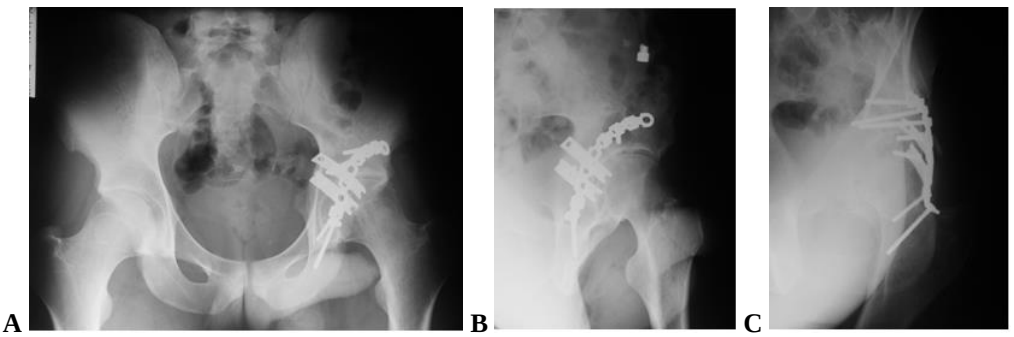

Fig. 4. 12 months follow-up: **A** - anteroposterior view**, B** – external oblique view, **C** – internal oblique view.

DISCUSSION

Despite the fact that posterior wall fractures are easy to treat, even with a 94–100% anatomical reduction rate, the percentage of excellent and good hip function scores represent only 68-82% (1, 2, 11). The difference between the radiological and clinical result can be explained due to comminution, marginal impaction and chondral lesions (12). In our series we obtained anatomical

and acceptable fracture reduction (according to Matta score) with very good and acceptable clinical score (according to Merle D'Aubigné-Postel score) in 86% of cases. This higher clinical score that we obtain could be the result of the short follow up period but is still an encouraging score.

The major challenge in the treatment of comminuted posterior wall fractures is reduction and stabilization of small fragments, because these fragments cannot be stabilized by interfragmentary screws due to their small size and/or the risk the screws to penetrate the joint surface. To solve this problem, Mast *et al.* (8), described the "spring plate" technique using a plate placed perpendicular to the fracture covered by a posterior column reconstruction plate. A biomechanical study showed that large size fragments of posterior wall fractures can be stabilized with 2 or more screws but when comminution occurs 1 screw and a reconstruction plate is needed (13). Goulet *et al.* (14) demonstrated in his biomechanical study that internal fixation with interfragmentary screws is weaker than internal fixation with reconstruction plate and the combination of the two techniques being the most rigid in transversely comminuted fractures and that internal fixation with reconstruction plate versus reconstruction plate associated with spring plate showed no increase in rigidity but seems to be better in concentrically comminuted fractures

The clinical studies that used only screw fixation in cases with one large fragment or sufficiently large fragments obtained good results, but they don't describe the minimum size of the fragment or size of the comminution (15, 16).

The spring plate technique is not so rigid as the association between interfragmentary screws and reconstruction plate, but is rigid enough (12, 14). Richter *et al.* (17) sustained that the spring plate acts as dynamic buttress, it is solid enough for fixation of small fragments, can be used alone without other implants reducing the necessary dissection and is ideal for fixing small periarticular fragments which cannot be fixed by screws. Using this technique, Ebraheim *et al.* (12) had good results and the fixation was stable enough for early range of motion and weight bearing.

The plates used as spring plate can be made out of one-third tubular plates, most often used, or are prefabricated (12, 17). Ziran *et al.* (18) suggested the use of a "T" plate (used for distal epiphyseal radius internal fixation) as a spring plate. Other types of plates used, like "cervical vertebral plates" have the advantage of increased screw density (19); locking reconstruction plates with the advantage of monocortical screws in the danger zone (20).

Although the number of patients is not great, we believe that this technique of internal fixation using one-third tubular plates as spring plate, is the best for comminuted posterior wall fractures even though it does not provide the best rigidity but enough stability and by the buttress effect during mobilization and loading helps modeling the acetabular joint surface. This technique does not require any extra special instrument, guides, larger dissection and is easy to learn and apply.

Heterotopic ossification Brooker type I and II were present in 4 cases (19%) and we did not do any prophylaxis. This percentage is lower or the same with other studies (12, 21) that used prophylaxis of heterotopic ossification.

Hip arthritis was present in 2 cases (10%), higher than other studies, were the rate of this complication is 4-7.5% (11, 22). The arthritis occurred in one case were the reduction was lost and one case were the fracture involved both columns and comminuted posterior wall fracture. Loss of

reduction was reported up to 26% (23) which seems very high compared to our 1% but is a small series and we selected only the cases treated using spring plate technique. The outcome of both columns fracture with and without posterior wall fracture was reported to be the same (24), so it seems that our hip arthritis was not correlated to this injury.

CONCLUSIONS

We believe that internal fixation of comminuted posterior wall fractures using the "spring plate" technique provides sufficient rigidity to allow rapid mobilization, eliminates the risk of joint penetration of the implants and by the "buttress" effect helps shape the joint surface. It is a simple, easy to learn and to use technique.

NEWS

HPV AND BREAST CANCER

Studies evaluating the presence of HPVs in breast cancer have generated considerable controversy. Investigating a relationship between HPV and breast cancer is a valid hypothesis for a number of reasons, such as the exposure of the mammary ducts to the external environment via the nipple areola complex that could provide an entry point for HPV infection. Also, most breast cancers originate from mammary duct epithelia. Di Lonardo *et al*. (1992) were the first to report the positive relationship between HPV and breast cancer, by demonstrating the presence of HPV in 29% of breast carcinoma. Since the first discovery, several studies have investigated and detected over 60% HPV in breast cancer tissue. On the contrary, opposing studies were reported the absence of HPV DNA in breast cancer and suggested it is improbable that HPV is associated with the development of breast carcinomas. In the current study, tissue specimens from a total 110 fresh abnormal breast tissues (including cancerous and non-cancerous) from women aged 25-82 years old were examined for the presence of DNA of 12 HR-HPV types using type-specific PCR. Sequencing was performed on PCR products which confirmed the amplification of HPV DNA. The BLAST analysis revealed 99% and 98% concordance of the HPV DNA sequences in breast tissue samples tested with the reference sequences for high risk HPV types. Additionally, the data obtained from the sequencing are consistent with PCR results and this further validates our findings on the detection of HPV DNA. The results of high-risk HPV typing showed that HPV-DNA was found in 42% of abnormal breast tissue specimens and 31% of benign and normal breast tissue specimens. The presence of high-risk HPV viral sequences and the expression of viral protein in malignant breast tissue highlight the importance of further studies to investigate and assess the possible viral mechanism in the pathogenesis of breast cancer. (Salman NA, Davies G, Majidy F, *et al*. Association of high-risk human papillomavirus and breast cancer: A UK based study. *Sci Rep*. 2017; 7: 43591).

CHEST TRAUMA: THE DROP THAT FILLED THE GLASS

CHEST TRAUMA: THE DROP THAT FILLED THE GLASS" (CASE REPORT) (Abstract): We present the case of a 50-year-old patient, smoker, alcohol user, with untreated stable angina pectoris who presented to the emergency department with severe chest pain which started about 4 hours earlier following a trauma by the fall of a solid object on his thorax. The anamnestic context requires the exclusion of a chest wall lesion, but at the same time it raises the problem of a heart lesion. Posttraumatic osteoarticular and pleuropulmonary lesions were not confirmed. The ECG pattern of acute anterior wall ST-segment elevation myocardial infarction and significant increase of highly sensitive troponin I (hs-TnI) drew our attention. Emergency echocardiography revealed anomalies of segmental left ventricular wall motion, moderate systolic dysfunction, and excluded other cardiac lesions. Primary percutaneous coronary intervention with drug-eluting stent is performed for thrombotic occlusion in the mid-segment of the left anterior descending coronary artery. The course was not complicated, but the left ventricular systolic dysfunction persisted. The presented case is particular due to the low prevalence of the posttraumatic acute myocardial infarction, mechanism of production, and diagnostic and therapeutic management issues. **Keywords**: POSTTRAUMATIC ACUTE MYOCARDIAL INFARCTION, CHEST TRAUMA, PRIMARY PCI.

The incidence of cardiac traumas caused by anteroposterior chest compression is increasing. Of these, contusions are much more frequent than cardiac injuries which often remain undiagnosed. The most common cardiac complications are arrhythmias, myocardial or valvular rupture, cardiac tamponade, and myocardial ischemia. Traumatic myocardial infarction caused by cardiac contusions is a rare but often fatal complication. The mechanism of production is both through direct myocardial injury and coronary artery injury. The prompt differential diagnosis and appropriate emergency management are essential for a favorable prognosis.

CASE REPORT

A 50-year-old patient, smoker (4-5 cigarettes per day) and a chronic alcohol user presented to the emergency department for severe, constrictive chest pain radiating posteriorly which started about 4 hours before presentation. These symptoms occurred after a chest trauma caused by the fall of a large solid object on his chest during work (he is a forester). The patient had no significant family history. He was

diagnosed with stable angina pectoris four years earlier but did not receive treatment. The anamnestic information about trauma required the exclusion of a chest wall lesion, but at the same raised the problem of a cardiac lesion. Objective examination did not reveal ecchymoses or rib fractures, lung sounds were normal, elements confirmed by the normal appearance of chest X-ray (fig. 1).

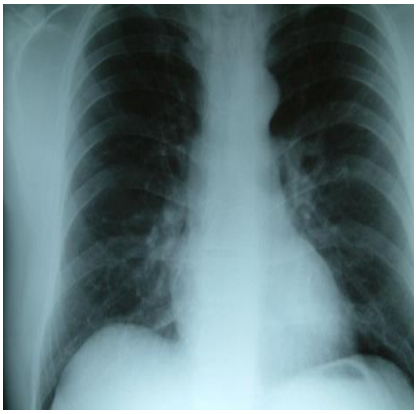

Fig. 1. Posterior-anterior chest X-ray. No bone and pleuropulmonary lesions, normal cardiothoracic ratio

The patient was hemodynamically stable (blood pressure of 140/80 mmHg, a resting heart rate of 64 beats per minute), no organic heart murmurs were detected, and radial pulse was symmetrical. The surprise but also the defining element for the diagnosis was the ECG suggestive of extensive acute anterior wall ST-segment elevation myocardial infarction (STEMI) (fig. 2).

The diagnosis of STEMI was supported by the prolonged chest pain and positive hs-TnI (2.4 ng/mL, normal values < 0.016 ng/mL). Emergency echocardiography provided consistent data for the positive diagnosis by highlighting akinesia of the apical half of the anterior wall and interventricular septum with moderate systolic dysfunction (EF of 35%). Echocardiography did not reveal acute valvular lesions, pericardial effusion and aortic dissection as secondary injuries to chest trauma. The patient was referred for primary percutaneous coronary intervention (PCI) (fig. 3A). The thrombotic occlusion was detected in the mid-segment of the left anterior descending artery (LAD). PCI with drug-eluting stent was performed successfully (fig. 3B) and TIMI 3 flow was achieved.

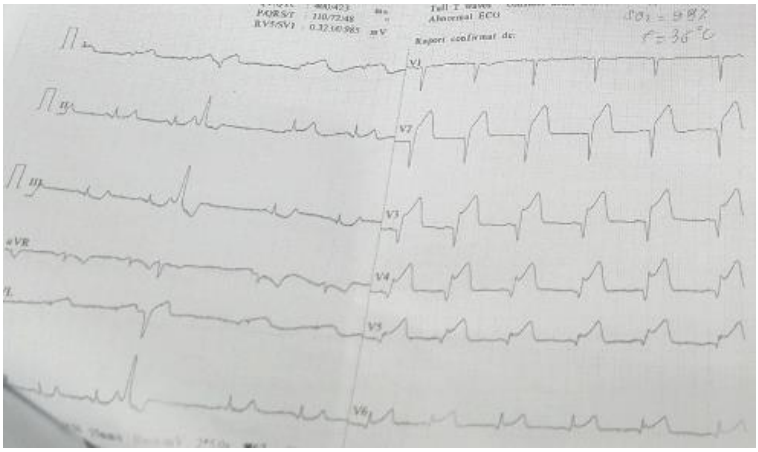

Fig. 2. ECG - extensive acute anterior wall acute myocardial infarction

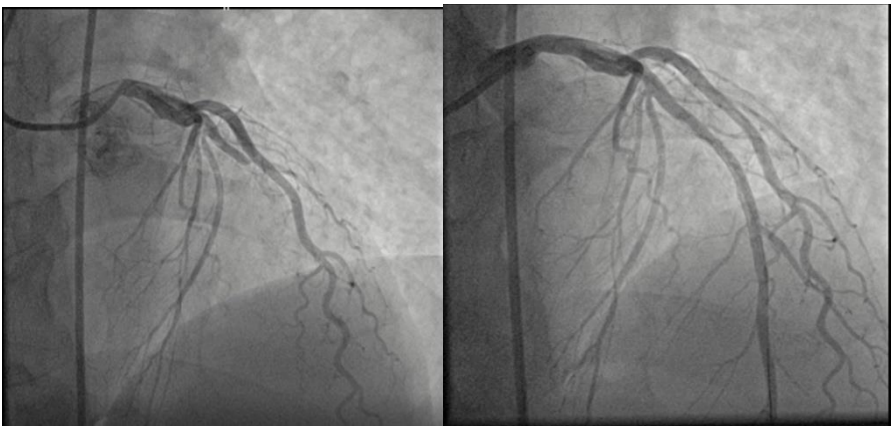

Fig. 3. A. Coronary angiography-right anterior oblique view

Thrombotic occlusion in the mid-segment of LAD. **B**. Post-stenting appearance

The course after revascularization was not complicated, the patient being hemodynamically stable, with no residual pectoral angina and no arrhythmias. ECG pattern was suggestive of subacute extensive anterior STEMI (fig. 4), and before discharge of chronic anteroseptal myocardial infarction.

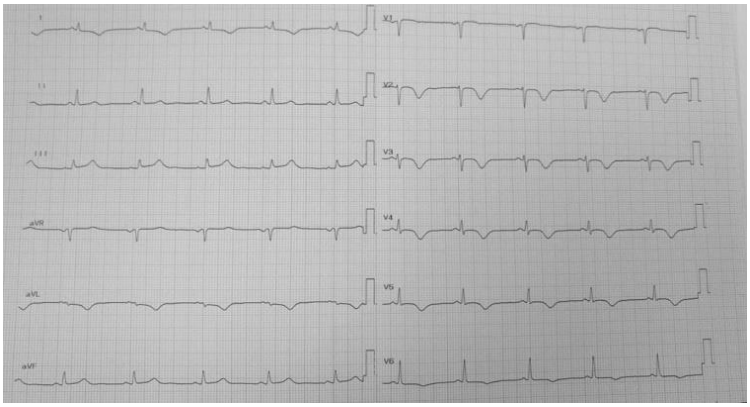

Fig. 4. ECG post PCI.
Appearance of subacute extensive anterior myocardial infarction

After revascularization, the balance of cardiovascular risk factors is completed. Total cholesterol and HDL-cholesterol were within normal ranges (200 mg/dL and 69 mg/dL respectively), but LDL-cholesterol above target values in a high cardiovascular risk patient (110 mg/dL), triglycerides 110 mg/dL, blood glucose level 94 mg/dL, creatinine 0.78 mg/dL were found. Worth mentioning was the persistence of echocardiographic features of systolic dysfunction (ejection fraction - EF of 35%). The patient was discharged with the recommendation of avoiding intense physical activity and high temperatures, eat a moderate sodium diet, and quit

smoking and drinking. Dual antiplatelet therapy with Aspirin 75 mg/day and Ticagrelor 90 mg b.i.d. for 12 months, Atorvastatin 80 mg/day, supplemented with the treatment of cardiac failure - Ramipril 5 mg/day, Bisoprolol 2.5 mg/day, a fixed-dose combination of furosemide and spironolactone 50/20 mg/day were recommended. A follow-up evaluation was scheduled at 3 months.

DISCUSSION

Cardiac injury after chest trauma is not very common but can be life-threatening. The prevalence is about 5-15% of chest traumas, 15% of them being documented at autopsy, but most of them remain undiagnosed. The most frequent cardiac complications are myocardial necrosis, arrhythmias and pericarditis or tamponade, frequently produced after road accidents (1). Acute myocardial infarction occurs in 5% of patients with blunt chest trauma, but it is associated with a significant risk of morbidity and mortality (2). The most frequent causes of coronary occlusion reported in the literature are *de novo* stenosis by external compression and subintimal edema, subintimal hemorrhage, spasm, thrombosis or rupture of a preexisting atherosclerotic plaque, compression by epicardial hematoma. Coronary artery laceration and dissection were also described after chest traumas (3, 4).

The most frequently involved vessel is the anterior descending artery, due to its anatomical position, being located proximal to the thoracic wall, as in the presented case. The right coronary artery is particularly vulnerable at its origin especially due to acceleration/deceleration injury. The circumflex artery and the left main trunk are rarely involved (5, 6) (tab. I).

TABLE I
Frequency of coronary artery involvement in chest trauma

Anterior descending artery	76%
Right coronary artery	12%
Circumflex artery	6%
Left main trunk	1%

The mechanisms by which posttraumatic cardiac injuries are produced are not very clear. Compression of the anterior thoracic wall along with the deceleration shear forces would be responsible for the arterial intimal injury (7, 8).

Our patient was a smoker and reported a history of untreated angina pectoris, which is likely to cause atherosclerotic lesions. However, *in situ* thrombosis cannot be excluded. Literature data mention the production of myocardial infarction several hours after trauma (9), as in the presented case. Patients with myocardial contusions may describe angina pain not relieved by analgesics or dyspnea, but these symptoms are nonspecific.

The investigation of blunt cardiac injuries always starts with a 12-lead ECG, a sensitive method considered the best predictor of diagnosis. In fact, 40-83% of patients with myocardial contusions have abnormal ECG. Therefore, ECG is a class I recommended diagnostic test for blunt cardiac injury (10). If ECG is abnormal, the cardiac enzymes (troponin I/T) can be measured in dynamics, although their positive predictive value is low in case of trauma. However, the association between normal troponin I/T and normal ECG at 4-6 hours after chest trauma rules out myocardial contusion (11, 12). For this reason, the determination of cardiac enzymes is considered a test with negative predictive value. According to the diagnosis algorithm proposed in the literature (13), if ECG and

troponin are abnormal another diagnostic method is required.

Echocardiography is considered the most useful and cost-effective (class II recommendations) because it can directly confirm the type of structural lesion and the aortic dissection (13). In some situations, transesophageal echocardiography is superior (13). In the presence of segmental wall motion abnormalities, the ECG changes are suggestive for STEMI and enzymatic dynamics confirms its diagnostic value. Cardiac enzymes have no high specificity in case of trauma, but correlated with ECG and echocardiography and, last but not least, with history may be valuable for diagnosis (11). The most useful one remains hs-TnI, levels above 1 ng/mL supporting a diagnosis of myocardial infarction in the presence of regional wall motion abnormalities. Finally, if ECG is abnormal and echocardiography shows regional wall motion abnormalities and a decreased EF, a coronary angiogram has to be performed (13). It can determine whether ECG and enzyme changes are caused by myocardial contusion *per se* or by the myocardial infarction secondary to a coronary artery injury.

Only if coronary angiogram is normal, nuclear imaging (SPECT, PET) may be indicated. The presence of concurrent perfusion and metabolism defects can make a diagnosis of myocardial infarction (14). To accurately identify the mechanism of myocardial infarction, advanced intracoronary imaging methods such as optical coherence tomography or intravascular ultrasound, unavailable in the presented case, may be used (15).

The persistence of systolic dysfunction after myocardial revascularization in a patient with a single coronary artery lesion and TIMI 3 flow raises the problem of a preexisting cardiac damage, most likely of toxic etiology, given the positive history of alcohol consumption. On the other hand, myocardial contusion *per se* can directly affect the systolic function by compromising myocardial perfusion.

The optimal management of posttraumatic myocardial infarction is not well defined because of the relatively low incidence of these cases and difficulty in conduction large randomized trials. Therefore, the decision must be made on a case-by-case basis considering the fragile balance between bleeding and thrombotic risks. Thrombolytic therapy required when optimal timing for primary PCI was exceeded is contraindicated due to the hemorrhagic risk of associated lesions. The preferred strategy remains as for any STEMI an emergency coronary angiography and reperfusion therapy. Revascularization by primary PCI remains the best treatment option in patients without internal bleeding, because it allows blood flow restoration in the culprit artery affected vessel and is minimally invasive (5-7, 15). A review of literature based on PubMed data on the prevalence and treatment of myocardial infarction after blunt chest trauma reported 24 cases (17 men and 7 women, mean age 43.6 ± 12.6 years) in the last 5 years (17). Of these, 3 patients (12.5%) were treated medically, 2 patients (8.3%) with coronary artery bypass grafting, and 1 patient (4.1%) received systemic thrombolysis after prolonged resuscitation. Urgent PCI was performed in 10 subjects (41.6%): 5 patients received a drug eluting stent, 4 patients a bare metal stent, and in one case the implanted device was not specified. Thromboaspiration was performed only in two cases. In contrast, 8 patients (33.3%) re-

ceived delayed PCI (24 hours to 15 days after trauma). This strategy was primarily adopted to avoid serious or fatal bleeding complications, those patients requiring noncardiac surgery (17).

It is recommended that all patients with documented posttraumatic cardiac injury should be reassessed after 3-6 months as late cardiac complications such as atrioventricular conduction disorders, cardiac rupture, heart failure, and pericarditis progressing to pericardial constriction may occur. As to the specific long-term treatment, there are controversies about the safety and usefulness of statin therapy in posttraumatic myocardial infarction (18). Thus, the administration of statins should be decided according to the cause and mechanism of myocardial infarction.

CONCLUSIONS

The possibility of coronary artery injury should be considered in all patients with anterior chest pain following blunt chest trauma, because late diagnosis and management can lead to serious complications or even death. Posttraumatic myocardial infarction remains a challenge because it raises the problem of the mechanism of production and has management particularities. The sequence ECG - cardiac enzymes – echocardiography - coronary angiography must be used according to the patient to differentiate the role of a blunt cardiac injury from a myocardial infarction secondary to a coronary lesion. Interdisciplinary collaboration is recommended, the interventional cardiologist being indispensable in management decisions.

NEWS

BALOXAVIR MARBOXIL: THE NEW INFLUENZA DRUG ON THE MARKET

Annually, influenza viruses have a major impact on global health, causing 3-5 million severe cases of disease and 1 million deaths. Although vaccines for influenza are available, poor annual vaccine coverage, low immunogenicity in the elderly population, and occasional vaccine mismatches means that they do not deliver adequate levels of protection. For this reason, influenza antiviral drugs are essential and are used for both treatment and prophylaxis. For the first time in nearly 20 years there is a new class of antiviral drug for influenza. The latest approved antiviral is baloxavir marboxil (trade name, Xofluza) which targets the endonuclease function of the viral PA polymerase subunit and prevents the transcription of viral mRNA. The most promising aspect of this new drug is its pharmacology which allows for effective treatment of influenza A or B virus infection with just a single dose. A clinical trial showed greater reductions in viral loads with baloxavir marboxil treatment compared with oseltamivir, although no difference in the time to alleviation of symptoms between these two drugs. Baloxavir marboxil was well tolerated with only 4.4% of patients reporting minor adverse events related to the trial regimen, such as diarrhea and nausea. A similar number of patients reported the same adverse events for the placebo (3.9%) and oseltamivir (8.4%) groups, mitigating any concern that these events are unique to baloxavir marboxil. Similarly, only a few non-serious adverse events were reported during phase I and phase II trials with baloxavir marboxil, including a phase I trial looking for adverse events in 18 healthy adults treated with combinations of baloxavir marboxil and oseltamivir. Future developmental milestones for baloxavir marboxil include approval for use in children under age 12, and in patients with risk factors for influenza complications. A phase III clinical trial to address the latter is underway (CAPSTONE-2). Also, the efficacy of baloxavir marboxil and NAI combination therapies and the ability to improve clinical outcome when starting treatment after 48 hours has yet to be evaluated in a clinical trial. With this new class of influenza drug comes exciting prospects for combination therapy with the neuraminidase inhibitors which may help to abate concerns about the development of resistance (O'Hanlon R., Shaw ML. Baloxavir marboxil: the new influenza drug on the market. *Current Opinion in Virology* 2019; 35: 14-18).

CLINICAL AND ECHOCARDIOGRAPHIC PROFILE IN PATIENTS WITH END STAGE LIVER DISEASE

CLINICAL AND ECHOCARDIOGRAPHIC PROFILE IN PATIENTS WITH END STAGE LIVER DISEASE (Abstract): The purpose of our study was to describe and better understand the clinical aspects of cirrhotic patients from a cardiologic perspective, to observe the correlations between clinical and echocardiography findings and to evaluate the prognostic impact of cardiac involvement in the end stage liver disease. **Material and methods**: We enrolled for this study a number of 83 patients that were devised according to MELD and Child-Pugh score. All study participants underwent a complete clinical examination and were assessed by echocardiography focusing on chambers dimensions, walls thickness, E/A ratio, left ventricular ejection fraction and pulmonary artery systolic pressure (PAPs). **Results:** The most frequent cardiac sign was edemas (34.9%), which was not correlated with the MELD score (p=0.118) but had an influence on the mortality rate (p=0.043). PAPs was higher among patients with edemas (mean value 29.34 mmHg; p=0.001), dyspnea (34 mmHg; p=0.012) and heart murmurs (36 mmHg; p=0.001) also if left atrium dilation was present (28.81±10.02 *vs.* 22.13±8.95, p=0.002). **Conclusions:** The echocardiographic parameters assessed in cirrhotic patients were not predictors of mortality and were not influenced by the severity of liver cirrhosis. **Keywords:** CIRRHOTIC CARDIOMYOPATHY, LIVER TRANSPLANT, PULMONARY ARTERY HYPERTENSION, LIVER CIRRHOSIS, ECHOCARDIOGRAPHY.

The close connection and interaction between the heart and the liver have been known for many years. The complex relationship between the two organs can be classified into several categories: heart diseases affecting the liver, liver diseases affecting the heart, including hepatopulmonary syndrome and portopulmonary arterial hypertension, and conditions affecting both the heart and the liver by having common etiological factors (1).

The end stage of liver disease has a systemic impact that negatively contributes to the patient prognostic. Cirrhotic cardiomyopathy (CCM) is defined as reduced contractility in condition of stress, diastolic dysfunction (DD) and associated electrophysiological abnormalities. Liver cirrhosis

is characterized by marked peripheral vasodilatation and a hyperdynamic circulation. In this hemodynamic context CCM is often subclinical and it is very easily overlooked. However, the cardiovascular events have a major contribution on morbidity and mortality associated with liver transplantation, being the third leading cause of death in liver recipients (2). Thus, we highlight the importance of early diagnosis of CCM by routine evaluation of the cardiovascular function in cirrhotic patients.

The aim of the study was to assess the echocardiographic parameters on cirrhotic patients according to the severity of the disease.

MATERIAL AND METHODS

Study population

The study was conducted as a cross-sectional analysis over a three-year period (2016-2019) and included patients with liver cirrhosis admitted in a tertiary center. A total of 83 cirrhotic patients (62 males) aged between 26-75 years, that had undergone a complete echocardiographic examination were evaluated. We excluded the cirrhotic patients with pre-existing cardiovascular disease. A close follow-up was performed and the mortality was checked during the first 12 months.

The diagnosis of cirrhosis was based on clinical, hemodynamic, biochemical parameters, ultrasound imaging. All the patients had a detailed medical history, physical examination, blood pressure measuring, electrocardiogram recording and echocardiography evaluation. Cardiac examination and echocardiography were performed by a single experienced cardiologist. The severity of liver disease was appreciated using Child - Pugh (CP) and Model of End-Stage Liver Disease (MELD) scores.

We excluded patients who refused to have a complete cardiological evaluation, patients with pathological conditions that prevented a correct echocardiographic examination (thoracic surgery, extreme obesity, severe osteo-articular chest pain), patients with neuro-psychiatric pathologies or special socio-cultural beliefs who refused a physical exam or who didn't sign the written consent.

The study was conducted in accordance with the Helsinki Declaration and all patients were consecutively enrolled to the study after providing written informed consent that was initially approved by the local Ethics Committee.

Echocardiographic parameters analysis

Transthoracic echocardiography was performed in all the patients. Measurements were made in M mode according to the European Society of Echocardiography. The following parameters were determined: diastolic diameter (Dd), systolic diameter (Ds), thickness of the walls. Ejection fraction (EF) was the most widely used parameter of global left ventricular systolic function. It was calculated using end-systolic and end-diastolic volumes, by the formula: $EF = (Dd^3 - Ds^3) \times 100 / Dd^3$ and we considered normal value EF between 60-80%. The visual estimation of the EF (eye balling) was used in parallel with the determinations using the diameters without significant differences. Diastolic function was appreciated in our study in 2D Echo and M Mode (dimensions and function of LA and LV, LV - wall thickness, the pattern of the interventricular septum (IVS) movement). Non-invasive assessment of DD was classically based on the echocardiographic analysis of mitral inflow pattern using pulsed-

wave Doppler. The impaired relaxation pattern is characterized by a decrease in E wave velocity, prolongation of E-wave deceleration time, and an increase in A wave velocity resulting in an inverted E/A ratio (< 1).

Statistical analysis

Statistical analysis was carried out using the *SPSS 20.0* software (SPSS Inc., Chicago, IL, USA). Data were expressed as mean ± standard deviation or number of cases with percentage, for continuous and ordinal variables. Cross-tabulation and Pearson Chi-Square test were used for describing the relationship between two categorical variables. The one-way analysis of variance (ANOVA) was used to determine the significant differences between the means of continuous variables and an independent categorical variable. For all data, a two-sided p value < 0.05 was considered statistically significant.

RESULTS

The study included 83 patients with liver cirrhosis, 56 patients in the age group of >50 years, the majority of patients being males (62 patients). In our study the etiology was mostly viral (virus B -6 patients; virus C - 29 patients, virus B+D - 23 patients) and alcoholic (16 patients, alcoholic and viral C -4 patients). We also had 5 patients with autoimmune etiology and one patient with cryptogenic cirrhosis. 31 patients (37. 35%) were Child-Pugh score C, and 32 patients (38.56%) Child-Pugh score B. The mean MELD score was 15.9±8.97, ranged between 7-30. Most of the patients (72.29%) were included on the transplant waiting list and 13 patients (15.67%) were transplanted, while 17 patients died (20.49%) during the study. The mortality rate was higher among patients with MELD score ≥ 20 (46.2%, p=0.002) and Child-Pugh class C (35.5%, p=0.008). All data can be found in table I.

TABLE I

MELD score correlations with echocardiographic parameters

Parameter	MELD<10 (n=17)	MELD=10-19 (n=40)	MELD≥20 (n=26)	p
EF (%), mean ± SD	56.47±12.76	59.85±10.45	63.92±7.24	0.060
LV Dd (mm), mean ± SD	47.94±8.25	49.00±7.30	47.88±6.76	0.795
IVS (mm), mean ± SD	11.12±1.55	10.71±1.29	10.96±1.37	0.551
LVPW (mm), mean ± SD	10.24±1.25	10.18±0.98	10.81±1.92	0.180
PASP (mmHg), mean ± SD	24.59±11.81	25.23±10.06	26.81±9.01	0.744
LA diameter (mm), mean ± SD	45.76±9.47	48.35±8.51	46.15±8.21	0.462
E/A ≤ 1, n, (%)	13 (76.5)	17 (42.5)	8 (30.8)	**0.010**
E/A >1, n, (%)	4 (23.5)	23 (57.5)	18 (69.2)	**0.010**
Viral etiology, n, (%)	15 (88.2)	28 (70.0)	14 (53.8)	**0.050**
Alcoholic etiology, n, (%)	2 (11.8)	5 (12.5)	8 (30.8)	0.056
Alcoholic and viral etiology, n, (%)	0 (0)	2 (5.0)	3 (11.5)	0.077
Mortality rate, n, (%)	2 (11.8)	3 (7.5)	12 (46.2)	**0.002**

Abbreviations: EF-ejection fraction; LV Dd- left ventricle diastolic diameter; IVS-interventricular septum; LVPW- left ventricle posterior wall; PAPS- pulmonary arterial systolic pressure; LA- left atrium; SD-standard deviation.

The echocardiographic assessment revealed the presence of LV hypertrophy in 27 patients (32.54%) with a moderate degree (LVPW between 12-13mm and IVS between 12-14mm). There were not significantly differences in the IVS or LVPW thickness between the MELD and CP subgroups. The LV Dd was abnormal in 15.6% of patients (between 59-70mm on males and 53-70mm on females), indicating a dilated cardiomyopathy. The most frequent etiology among patients with dilated LV was viral (42.9%-viral, 21.4% - toxic, 28.6% - viral and alcoholic), but the viral cause did not have a considerable influence on LV diameter. The alcoholic etiology was present in only 21.4% of the patients with dilated LV, in comparison with 17.4% patients without dilated LV (p=0.052). The LV dilation was associated with atrial fibrillation (AF) (21.4% *vs.* 4.3%, p=0.050) and a lower LVEF (49.43±17.51 *vs.* 62.67±6.36, p=0.001), but did not have an influence on the mortality rate (21,4% *vs.* 20,3%, p=0,693). The values of LV Dd did not significantly differ between the MELD (p=0.795) or CP class (p=0.682) subgroups. Also, 78,6% of patients with dilated LV associated a dilated LA (p=0.024). Table 1 shows MELD score correlations with echocardiographic parameters.

The LA was dilated in 43 patients (51.81%), without being influenced by the etiology or the liver disease severity, with similar values of LA diameter among MELD (p=0.462) and CP class (p=0.130) subgroups. Dilated LA was associated with significantly higher values of PASP (28.81±10.02 *vs.* 22.13±8.95, p=0.002) and IVS thickness (11.26±1.30 *vs.* 10.46±1.33, p=0.007), but without correlation with the mortality rate (18.6% *vs.* 22.5%, p=0.738). AF was with predilection more present in patients with dilated LA (p=0,004). The E/A ratio did not differ significantly depending on the LA dilation (p=0.45).

In our study group, 55 patients (66.27%) presented valvular regurgitations (mitral, tricuspid, aortic, pulmonary), the most frequent being mitral regurgitation in 45 patients, followed by tricuspid regurgitation in 39 patients.

Pulmonary artery hypertension (PAH), as PASP >35mmHg, was present in 41 patients (49.40%). PASP was significantly more elevated among patients with edemas (29.34 mmHg; p=0,001), dyspnea (34 mmHg; p=0.012) and heart murmurs (36 mmHg; p=0.001). The PASP did not correlated with CP score (r= +0.033; R^2=0.0011; p=0.769) or MELD score (r= +0.038; R^2=0.0015; p=0.730). Also, there was not any statistically association between the value of PASP and mortality rate (p=0.606) or cirrhosis etiology (p=0.402).

The EF ranged between 15-80% with an average value of 60.49 ± 10.30%. 59 patients (71.09%) had a normal EF. A systolic dysfunction with an EF ≤50% was identified in 11 patients (13.26%), while 12 patients (14.46%) from the study group presented a hyperkinetic heart with EF ≥80%. The values for EF were slightly higher in the MELD≥20 (p=0.060) and CP class C subgroups, but without significantly differences (p=0.183).

The E/A ratio was >1 in 45 patients (54.22%) and ≤1 in 38 patients (45.79%) from the study group. E/A ratio >2 suggestive for a restrictive diastolic pattern was not identified in our patients. The E/A ratio ≤1 was more frequently present in patients with MELD score<10 compared with the two others MELD subgroups (76.5% *vs.* 42.5% *vs.* 30.8%, p=0.010). On the contrary, the E/A ratio >1 prevailed in cases with

MELD scores >20 (23.5% *vs.* 57.5% *vs.* 69.2%, p=0.010). The mortality rate was not influenced by the E/A ratio (26.3% *vs.* 15.6%, p=0.664).

The heart rate (HR) ranged between 50-110 beats/min, the average HR was 70.82 ± 11.23, 77 patients from the total group study were in sinus rhythm (92.8%), 7 patients (8.45%) had atrial tachycardia, only 6 patients were on AF (7.2%) and 7 patients (8.45%) had premature ventricular contraction. There was observed an indirect of moderate intensity correlation between the values of HR and EF (r= -0.286; p=0.009), 28.6% patients associated elevated HR with reduced EF.

DISCUSSION

The complex pathophysiological changes that take place along with liver cirrhosis also have an impact on the cardiovascular system in the form of CCM. The diagnosis of CCM involves an impaired contractile responsiveness to stress, DD and electrophysiological abnormalities in the absence of known cardiac disease. By its effects, according to recent studies, this entity was associated with poor survival outcome independently of liver disease severity, being an important prognostic factor, which brings into focus the need for a positive diagnosis at the earliest possible stage (3).

Due to marked peripheral and splanchnic vasodilatation in the context of increased production/activity of vasodilator factors and decreased vascular reactivity to vasoconstrictors, cirrhotic patients may display low BP with a bounding, raised pulse and symptoms of reddish skin, palmar erythema. In early stages, the reduction in systemic vascular resistance is compensated by an increase in cardiac output and activation of vasoconstrictor systems which may keep the effective arterial blood volume and the arterial blood pressure in the normal range (4, 5).

The echocardiographic exam included measurements of heart chambers, the evaluation of systolic and diastolic function and the quantification of PASP. The end-stage liver disease is known to induce remodeling of the heart with structural changes: LV hypertrophy, LV dilation, LA enlargement (6-8). In the current study, LV hypertrophy was present in only 27 patients, and we did not obtain a correlation between the thickness of IVS or LVPW and MELD/CP scores. The discrepancy between our study results and previous studies may be explained by the small number of cases, larger studies being needed for a more precise correlation.

The DD often present in cirrhotic patients may cause an increase in LA pressure or volume overload which may lead to LA remodeling and enlargement (9). Being related with a higher risk of AF and cardiovascular events, the high prognostic value of LA enlargement in population without cirrhosis is already known (10-14). Hence, we assessed the LA size for predicting outcome in patients with end stage liver disease. Our study showed that patients with LA dilation had higher rates of AF and greater values of PASP. Even if in our cases the mortality rates were not influenced by the LA size, maybe due to the relatively small study group and limited follow up time, the presence of AF, PAH and dyspnea in these patients may predict a negative outcome. The LA enlargement prognostic significance in cirrhosis is supported by a study that identified dilated LA as a predictor of hepatopulmonary syndrome (15). Also, another study published by Merli *et al*. concluded there is an influ-

enced 2 years survival among liver cirrhotic patients by LA volume and LV mass (16). The importance of routine evaluation of the LA size, which reflects the cumulative effect of LV filling pressure over time, may be even greater than the assessment of diastolic function by Doppler parameters that may be altered by transient changes in loading conditions.

End stage liver disease may frequently associate DD. The pathogenesis may involve the sodium and fluid retention present in cirrhosis and modulation collagen configuration, followed by a combination of mild myocardial hypertrophy, fibrosis, and subendothelial edema (17-19).In our study we evaluated the diastolic function by trans mitral Doppler echocardiography, as an easily accessible diagnostic tool. There is a lot of scientific data supporting the significant relation between DD and survival rates in end stage liver disease (20, 21). Our results showed contrary to our expectation, a MELD score ≥20 associated with an E/A ratio >1, and a linear decrease in the E/A ratio (≤1) and the MELD score. From these data, we can't exclude the presence of DD in patients with end stage liver disease, as E/A ratio >1 may reflect a normal ventricular relaxation and diastolic function, but also a moderate DD in pseudo normal phase. If the latter is the case, than the grade of DD was significantly influenced by the advanced liver disease, results consistent with the larger studies on this topic (22). However, for more accurate results the preferred imaging techniques are tissue Doppler echocardiography and cardiac magnetic resonance imaging (20).

Most often, due to reduced afterload, the systolic ventricular function is normal at rest, being evident only in condition of physical or pharmacological stress (23-25). Most of the patients from our study group had a normal EF, only a minority of cases presenting impaired systolic function. However, for a better appreciation of subclinical systolic dysfunction the most sensitive and accurate method is 2D speckle-tracking strain analysis which was not available at the moment of our study (26).

PAH may be a common complication in the end stage liver disease, part of the portopulmonary hypertension (POPH) syndrome. The main pathological abnormality consist in progressive pulmonary vascular remodeling due to multiple changes present in cirrhosis (27-29). In the present study, almost half of the patients associated PAH (49.40%), but this parameter was not correlated with the severity of liver disease or mortality rate. Other studies also confirmed that the severity of liver disease may not be a factor of influence for the PASP (30).The clinical signs of right-heart failure may be an essential clue of PAH. All of our patients that presented high PASP values associated clinical manifestations like dyspnea, edemas, heart murmurs. The presence of edemas was also associated in our patients with higher mortality rates, which may be an indirect outcome predictor. The measurement of PASP is particularly important in patients undergoing liver transplant (LT), as the perioperative mortality rate is higher in patients associating PAH or POPH. Also, these patients are candidates for vasomodulator therapy which may improve long term survival (31, 32).

Our study has several limitations. Although the LA diameter is more widely employed in clinical practice, the measurement of LA volume is a more reliable estimator of LA size and a more accurate predictor of cardiovascular events. For a proper evaluation of systolic LV function

in cirrhotic patients the recommendations are to study the EF after an induced stress, and by 2D speckle tracking strain analysis as well. Also, the diastolic dysfunction may be better appreciated if the tissue Doppler is applied.

CONCLUSIONS

In the setting of end stage liver cirrhosis, the coexisting cirrhotic cardiomyopathy may have an impact on the overall prognosis and liver transplant success. Thus, the screening and monitoring of the cardiac function in cirrhotic patients is mandatory, even if they are asymptomatic. The echocardiographic assessment may bring valuable information concerning the impact of the disease on cardiovascular system. In our study, the echocardiographic parameters were not predictors of mortality and were not influenced by the severity of liver cirrhosis.

PRACTICAL ASPECTS REGARDING ORAL SEPSIS (Abstract): Infections of the oral cavity are an important morbidity problem due to their frequency, their pluribacterial ethiology as well as their potential severe evolution, especially with the immunodepressive. The odontogenic infections are considered to be the cause of 40% of the deep throat infections. The infections of the submentonier space occur through direct extension from the mandibular incisors, those of the sublingual space start from the anterior mandibular teeth and those of the retrofaringian space start from the mandibular molar teeth. **Material and method**: The present study included 24 pacients diagnosed with oral sepsis in Iaşi Infectious Diseases Clinic. We analysed the ethiology and the clinical response to the administered antibiotherapy. **Results**: In several immunodepressed patients (with diabetus melitus, neutropenia, liver disfunction, carcinomas, tuberculosis) was noted sistemic evolution of odontogenic infection and they mainly came from the Surgery Clinics, where surgery was performed for the drainage of collections. Etiology was confirmed în 8 cases reflecting normal oropharyngeal flora. These infections were treated with antibiotics în synergistic combinations (betalactamines, quinolones, Cloramfenicol) with good results în 19 cases. **Conclusion**: Infections of the oral cavity are an important morbidity problem due to their frequency, their pluribacterial origin as well as their potential severe evolution, especially in immunodepressed patients. **Key words**: ORAL INFECTIONS, ORAL SEPSIS

CORRELATIONS BETWEEN GRAYSCALE AND HISTOPATHOLOGICAL PROPRIETIES OF CAROTID ATHEROSCLEROTIC PLAQUE

CORRELATIONS BETWEEN GRAYSCALE AND HISTOPATHOLOGICAL PROPRIETIES OF CAROTID ATHEROSCLEROTIC PLAQUE (Abstract): Identifying patients at risk for ischemic cerebral events is an important concern for vascular surgeons. Previous studies have identified the ultrasonic echo lucent plaques as vulnerable, with a higher probability to cause transient ischemic attacks (TIAs) or ischemic strokes. Grayscale median (GSM) is an ultrasound-based risk marker that measures atherosclerotic plaque echogenicity. Its value is still disputed in the literature. **Aim:** This prospective study aimed to determine if GSM is a good predictor for carotid plaque vulnerability. **Material and methods:** Included in this study were 49 consecutive patients with indication for carotid endarterectomy (CEA). Ultrasound scans were performed on admission and stenosis was measured. In all study patients GSM was measured on the ultrasound-acquired images. CEA was performed and the collected specimens sent for histopathologic examination. Ultrasound and histopathological findings were compared. **Results:** GSM measured after image normalization revealed a high heterogeneity of carotid plaques (median 48, range 8-130). Of the total 49 carotid atherosclerotic plaques examined 14 presented complications, being classified as unstable lesions, *American Heart Association* (AHA) type VI. GSM < 37 strongly correlated with lipid-rich necrotic core (LRNC), risk factor for plaque vulnerability. No correlation was found between GSM and any other histopathological findings (GSM vs type V/VI plaque ($p = 0.838$), GSM vs other histopathological markers of plaque instability such as ulceration ($p = 0.73$) and intraplaque hemorrhage ($p = 0.29$)). **Conclusions:** Although ultrasound remains the best non-invasive method for the assessment of carotid atherosclerotic plaques, GSM measurement can be time-consuming and has little additional value in assessing plaque vulnerability.
Keywords: GRAYSCALE, CAROTID ATHERO-SCLEROTIC PLAQUE.

The high rate of strokes, 1.4 million/year and consequently the high mortality of 1.1 million/year among Europe citizens is alarming (1, 2, 3). The most common cause of TIA or stroke is carotid artery and vertebral artery atherosclerosis, or thrombosis and the neurological deficit can occur suddenly, in "full health" (4). The

management of atherosclerotic carotid and vertebral artery disease is one of the most studied and discussed topic in the last years at each international vascular surgery meeting and was the topic of 2 major trials: The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and The European Carotid Surgery trial (ECST) (5, 6). Identifying patients at risk for ischemic cerebral events is an important concern for vascular surgeons. Ultrasound is preferred for carotid artery imaging due to its accessibility, low cost and non-invasiveness (1). The association of B-mode and Doppler color flow imaging increases the possibility of quantifying the degree of stenosis (1, 7).

Previous studies have identified the ultrasonic echo lucent plaques as vulnerable and associated them with a higher probability of causing TIAs or ischemic strokes. GSM is an ultrasound-based risk marker that measures atherosclerotic plaque echogenicity (8, 9). Its value is still disputed in the literature. This prospective study aimed to determine if GSM is a predictor of carotid plaque vulnerability.

MATERIAL AND METHOD

Included in this study were 49 consecutive patients admitted to the Department of Vascular Surgery of the Iasi "Sf. Spiridon" County Clinical Emergency Hospital between January 2015 and April 2018 with indication for CEA. There were 38 male and 11 female patients, median age 66 years old (range 54-80), 34 patients being over age 65 years at the time of diagnosis.

The patients were selected from the cases with a high probability of advanced internal carotid artery (ICA) lesion referred from neurology departments, and from those with peripheral vascular disease already admitted to our department who screened positive for significant carotid artery stenosis.

The inclusion criteria were asymptomatic ICA stenosis greater than 70%, recent history of transient ischemic attack (TIA) and ICA stenosis of 50-99% with a history of stroke maintaining self-sufficiency.

The exclusion criteria were autoimmune diseases, hypothyroidism, osteoporosis, hepatic insufficiency (GOT higher than 2.5 U/L), chronic renal disease (creatinine above 2.0 mg/dL), ischemic heart disease classes III, IV NYHA, atrial fibrillation, malignancies (10).

All patients underwent a new Doppler ultrasound examination using a Siemens X 700 ultrasound system. B-mode settings for carotid exploration were saved and used each time trying to ensure uniformity throughout the study (fig. 1).

Patients were examined supine with the neck rotated 45 degrees to the opposite side. A peripheral vascular transducer was used.

Carotid arteries were examined bilaterally, both in transverse and longitudinal planes (using an angle < 60°). Stenosis was measured according to the NASCET method and was calculated as the ratio between minimal residual lumen diameter at the stenosis as the numerator and the diameter of the disease-free ICA segment above the stenosis (where the vessel walls were approximately parallel) as denominator, in correlation with Intrastenotic flow (5, 7). The images were stored and transferred to a computer in order to calculate GSM for all study patients.

All images were normalized according to the method proposed by El-Atrozy *et al*. in order to eliminate gain-induced variability of echogenicity (9). The enhanced ultrasound images were processed using the computer software Adobe Photoshop and

selecting two reference points: blood (black) and adventitia (white) (fig. 2). The GSM of blood was set to 0, while the GSM of adventitia was set to 255. To determine the GSM for each carotid plaque the best segment for visualization was selected followed by the use of the histogram function of the software (9, 10) (fig. 3).

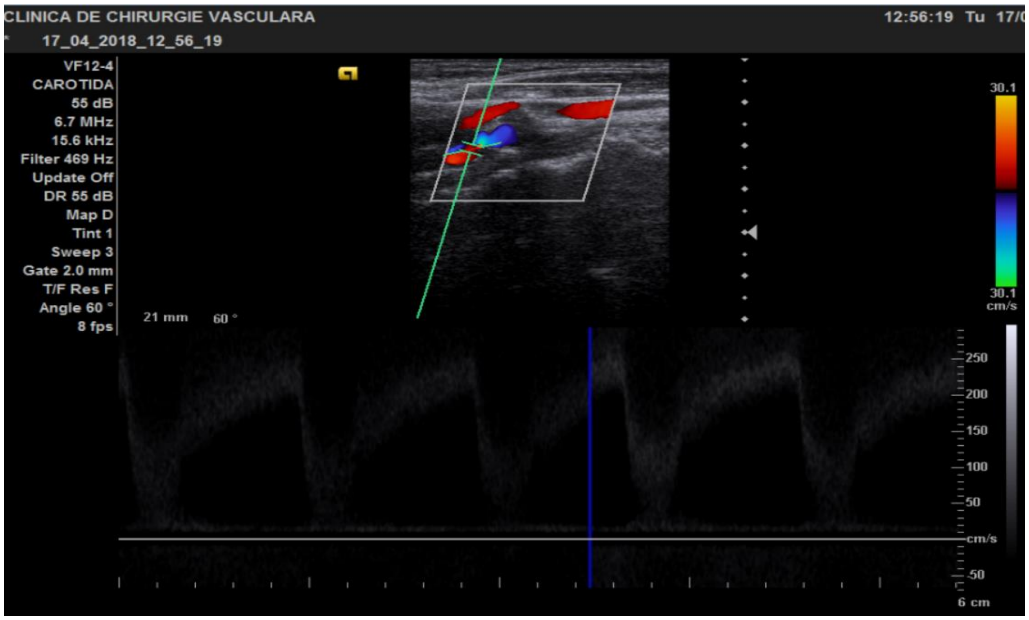

Fig. 1. Intrastenotic blood flow velocity at ICA bifurcation

Fig. 2. Post-normalization US image

Fig. 3. Histogram acquisition returning GSM value

All patients underwent carotid endarterectomy and patch angioplasty. Carotid endarterectomy specimens were processed by the standard paraffin embedded histology technique at the Histology Laboratory of the Iasi University of Medicine and Pharmacy. For each fragment, representative sections were selected and stained with

hematoxylin and eosin. The lesions were analyzed by two pathologists who classified the atherosclerotic plaques according to the AHA criteria (11).

The microscopic examination of carotid ATS plaques was focused on three main components, namely the cells (smooth muscle cells, macrophages and other leukocytes), extracellular matrix and intra- and extracellular lipids. Also determined was the presence or absence of the vulnerability factors (inflammation, LRNC, intraplaque hemorrhage or ulceration).

According to the histological criteria, the carotid ATS plaques belonged to two categories: stable, that includes type IV (atheroma) and type V (fibroatheroma) AHA lesions, and vulnerable, that comprises type VI AHA lesions (with erosions of the endothelium or fibrous cap, ulceration or intraplaque hemorrhage).

Statistical analysis was performed using *SPSS* software, Chi square descriptive test compared the ultrasound vulnerable plaques with GSM <=37 with the histopathologicaly-proven vulnerable plaques, AHA class VI.

RESULTS

Ultrasound scanning diagnosed 33 patients with 70-99% carotid stenosis, 14 patients with 60-69% and only 2 patients with 50-59% carotid stenosis, the last 2 patients having an indication for carotid endarterectomy due to recent symptomatology.

GSM measured after ultrasound image normalization revealed a high grade of heterogeneity of plaques. GSM ranged from 8 to 130, median 48 (tab. I).

Values in the first quartile ranged from 8 to 37. Unstable plaques were more heterogenic, with higher transparency and lower GSM than stable plaques. Quartile 25 included 13 plaques with increased ultrasound-based vulnerability and higher echo transparency. Quartile 50 and Quartile 75 included 36 echogenic, stable plaques according to ultrasound criteria.

TABLE I
GSM value quartile distribution

Min	Q25	Median	Q75	Max
8	37	48	59	130

Of the total of 49 carotid ATS plaques, 14 were classified as unstable AHA type VI lesions (fig. 4, fig. 5), with the following complications: intraplaque hemorrhage caused by the rupture of vessels in the granulation tissue of the atheroma in 2 cases, bleeding and ulceration in 5 cases and areas of erosion or irregular endothelial ulceration caused by plaque necrosis in 7 cases. The other 35 plaques were considered stable AHA type V lesions.

Inflammation and necrosis of the atheromatous core, considered risk factors for plaque vulnerability, were found in 17 and 13 lesions, respectively.

Dystrophic calcification was present in 39 of the 49 ATS lesions.

The plaques classified as vulnerable/stable by GSM and according to histopathological criteria were compared assuming that a lower GSM will be associated with histopathological plaque instability (tab. II).

We found no direct correlation either

between GSM (<=37 *vs.* >37) and type V or type VI plaque (p = 0.838), or the presence of each histopathological instability marker, namely ulceration (p = 0.73) and intraplaque hemorrhage (p = 0.29). Also, no statistically significant differences were found between GSM values and inflammation (p = 0.739).

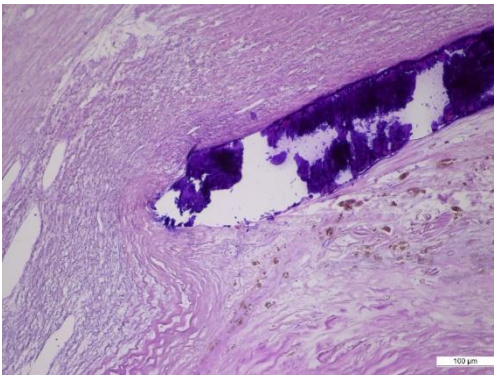

Fig. 4. Fibro lipidic plaque-compact calcification, destruction of internal elastic lamina (IEL) and marked compression of the media; adjacent to macrophage calcification loaded with hemosiderin pigment and neovascularization components, HEx100

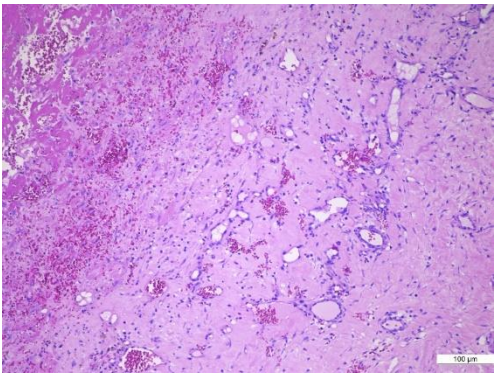

Fig. 5. Fibro lipidic plaque-intraplaque hemorrhage, numerous capillaries of neoangiogenesis, associated inflammatory infiltrate, HEx100.

TABLE II

GSM vs AHA plaque type - Cross tabulation

	Histopathological type		TOTAL
	Stabile	Vulnerable	
GSM>=37 0 →	26	10	36
GSM<37 1 →	9	4	13
TOTAL	35	14	49

GSM<37 strongly correlates independently with lipid-rich necrotic core, a morphological risk factor for plaque vulnerability. Of the 49 carotid plaques 13 showed signs of necrosis and 8 of these had GSM < 37 (p = 0.01).

DISCUSSION

Although the histopathologic examination is the "gold standard" for identifying and staging ATS lesions, this examination can be performed only postoperatively as confirmation based on the morphological substrate. In this context, a constant concern of specialists in vascular surgery is the implementation of alternative non-invasive diagnostic methods, which to allow the identification of vulnerable carotid ATS lesions. The rapid development of imaging techniques (Doppler ultrasound, carotid angiography, angio-CT, angio-MRI) has led to real progress, facilitating the primary

diagnosis and guiding the surgeon in making a therapeutic decision. Duplex ultrasound is "the firs line" imaging method for carotid artery (1). The Society of Radiologists recommended during the 2003 Ultrasound Consensus Conference that the final carotid artery ultrasound report should include velocity measurements, grayscale and color Doppler findings (12).

The relationship between echolucent plaque, plaque instability and presence of symptoms is proven (13). Echolucent plaques are more prone to rupture than dense fibrous echogenic plaques and are more common in patients with symptomatic cerebrovascular disease (14, 15).

Plaques with a higher GSM score are predominantly calcified plaques and are more stable and associated with a lower rate of cerebrovascular events (8). The GSM median of 48 and also the maximum at 130 show that most of our study patients had echogenic plaques. Also, in comparison with the results from other studies, our study showed higher median GSM values (8, 10). This is a consequence of the incidental discovery of carotid stenosis and that patients tend to present with more advanced disease or long after the symptomatic period (the first 6 months after an ischemic event). This fact is also confirmed by the predominant presence of AHA type V plaques in our study group.

Accumulation of lipid-rich necrotic debris and smooth muscle cells are present in advanced carotid plaques. Unstable plaques usually have a thin fibrous cap with a necrotic core situated juxta luminal. Our study supports a prior finding that lower GSM values are associated with lipid-rich necrotic core (16, 17). In presence of ulceration the necrotic core is exposed, the ATS plaque is vulnerable, predisposing to thromboembolic events.

However, full overlap of diagnostic imaging classes with histopathologic diagnosis classes has not been obtained, yet. Our study highlights the discrepancies between the classification of the plaques into the unstable, vulnerable versus stable categories by using ultrasound and histology, respectively. Our results demonstrate the limitation of ultrasound imaging for the assessment of plaque vulnerability. Despite the great benefits of ultrasound examination, as a non-invasive method, the vascular surgeon must be aware that GSM results cannot offer a perfect, point to point mirror of the morphological background that characterizes the plaques in their biological environment.

No carotid restenosis was detected during the first 12 months of ultrasound follow-up. The patients are still under surveillance, the follow-up aiming to detect the possible occurrence of restenosis at 24-year follow-up and to correlate the recurrence with GSM and histological characteristics.

CONCLUSIONS

High-grade carotid stenosis, GSM higher than 37, and AHA type V carotid ATS plaques predominantly identified in our study group show that patients tend to present with more advanced disease. GSM < 37 strongly correlates with intraplaque necrosis, but in the absence of other correlations with the histopathological vulnerable plaque characteristics it leads to the conclusion that although ultrasound remains the best non-invasive method for assessing the carotid ATS plaques, GSM measurement can be time-consuming with little additional value in evaluating plaque vulnerability.

THE MANAGEMENT OF A HOSPITAL-ACQUIRED INFLUENZA A H_1N_1 OUTBREAK IN ONCOLOGICAL PATIENTS. A CASE SERIES REPORT (Abstract): Despite prevailing concerns about the risk of influenza infection in immunocompromised patients, the actual rate and effect of infection in this population are not well characterized. We report a fulminant course of a hospital-acquired influenza AH_1N_1 infection in a public hospital for oncological patients. From a total of 60 persons (40 patients and 20 symptomatic health care workers - HCWs) screened by collecting nasal and pharyngeal swab samples, a number of 33 (24 patients and 9 HCWs) were found positive for respiratory viruses. Of them, 23 cases had influenza A virus (20 patients and 3 HCWs), all contacts with in-hospital influenza cases. The 4 first cases were diagnosed with influenza type A and subtype H_1N_1. In the epidemiological context we presumed all the other influenza A patients had the subtype H_1N_1. 9 influenza A patients were managed in the ICU: 5 patients for severe and 4 patients for mild/moderate ARDS. Oseltamivir treatment was instituted in all symptomatic patients and HCWs and in asymptomatic high-risk immune-compromised contacts. All ICU influenza patients and contacts were strictly isolated, had dedicated vaccinated HCWs wearing protective equipment and received oseltamivir treatment for prolonged periods until virus clearance or death. 5 patients died: 3 patients due to severe ARDS and intractable hypoxemia and 2 patients due to unrelated causes. The influenza-related death occurred in the first patients due to late diagnosis and late antiviral treatment institution. The epidemiological measures are described along with the hospital-acquired influenza outbreak course. **Keywords:** INFLUENZA, OUTBREAK**,** ONCOLOGIC.

The influenza virus is one of the most common human respiratory viruses associated with recurrent infections, which results in high population morbidity and, in the case of seasonal influenza, high mortality (1).

In March 2009, the influenza AH_1N_1 virus strain produced an outbreak of febrile respiratory infection worldwide and few months later World Health Organization declared influenza AH_1N_1 pandemic: more than 500,000 cases were reported in more than 214 countries and there were 18,849 deaths in that period (2).

High rates of influenza infection and

complications occur among people with impaired immune defense. Despite prevailing concerns about the risk of influenza infection in this type of patients, the actual rate and effect of infection in this population are not well characterized (3). Also, it is difficult to diagnose acute influenza infection in immunocompromised patients, who frequently develop neutropenic fever and are able to develop infections with almost any known pathogen. Doctors should stay alert to the possibility of influenza infection, especially in febrile immunocompromised patients during annual epidemic and should initiate antiviral treatment without delay (4). Influenza mortality is very high among this population, with reported case fatalities among cancer patients of 5 to 33% (5, 6, 7, 8).

CASE SERIES REPORT

We retrospectively recorded features of an influenza outbreak in the Regional Institute of Oncology (RIO) Iași, Romania during January-February 2018.

RIO Iași is a public 300 bed university affiliated hospital, dedicated to oncological patients and consists of 7 departments (Oncology, Hemato-oncology, Radiotherapy, Surgery, Anesthesia and Intensive Care and Palliation), some of them sharing the same floor. Patients are located in 1 to 4 bed wards. At the beginning of the influenza outbreak, 209 patients had long-term hospitalization. At that time, influenza viral infection was not reported in the city of Iași and our institution had no virus detection test, nor oseltamivir drug in the hospital's pharmacy.

Definitions - An **influenza A viral infection** was defined in a person, patient or health care worker (HCW), with an acute respiratory illness compatible with influenza A and confirmed by a positive polymerase chain reaction (PCR) test.

A **hospital-acquired influenza A viral infection** was defined in a person, patient or HCW, who developed symptoms 48 h following hospital admission or contact exposure in the hospital.

An **influenza A viral carrier** was an asymptomatic person with positive PCR test.

We used the Cepheid Xpert Xpress Flu/RSV assay, which is an automated, multiplex real-time, reverse transcriptase PCR assay intended for the in vitro qualitative detection and differentiation of respiratory viruses (influenza A, B, and respiratory syncytial virus).

From a total of 60 persons (40 patients and 20 symptomatic HCWs) screened by collecting nasal and pharyngeal swab samples, a number of 33 (24 patients and 9 HCWs) were found positive for respiratory viruses.

Of them, 23 cases were positive for influenza A virus, 2 influenza A and B virus, 6 influenza B virus, 1 influenza B and syncytial respiratory virus and 1 syncytial respiratory virus.

Out of the 23 influenza A cases there were 20 patients and 3 HCWs.

Out of the 2-concomitant influenza A and B cases: 1 patient and 1 HCW.

The infected HCWs consisted of 1 ICU nurse and 3 auxiliary ICU personnel, having mild/moderate illness treated at home, all contacts with the first ICU case (fig. 1).

Our first case was a 33-years-old male, diagnosed with a high-risk T cell acute lymphoblastic leukemia treated with induction chemotherapy in June 2017 and consolidation courses in September 2017. He was hospitalized from the 9th of January 2018 in Hemato-oncology Department for

continuation of consolidation chemotherapy and developed medullar aplasia on the 20th of January. On the 21st of January 2018 he was admitted to ICU for severe acute respiratory failure, 4 days after the onset of respiratory symptoms. Unlike the majority of immune-compromised patients admitted to our ICU with septic shock and multiple organ dysfunction, This patient had severe isolated acute respiratory distress syndrome (ARDS) caused by an interstitial pneumonia with negative results at direct microscopy, broncho-alveolar lavage cultures, broncho-alveolar lavage PCR for *Aspergillus spp.* and *Mycobacterium tuberculosis*. The clinical data and the negative respiratory cultures raised the suspicion of influenza infection. On the 25th of January „Dr. I. Cantacuzino" National Institute of Research-Development for Microbiology and Immunology, Bucharest confirmed the influenza type A subtype H_1N_1 infection. A hospital epidemiological alert was instituted considering the nosocomial type of the infection and the presence of high risk immunocompromised oncological patients.

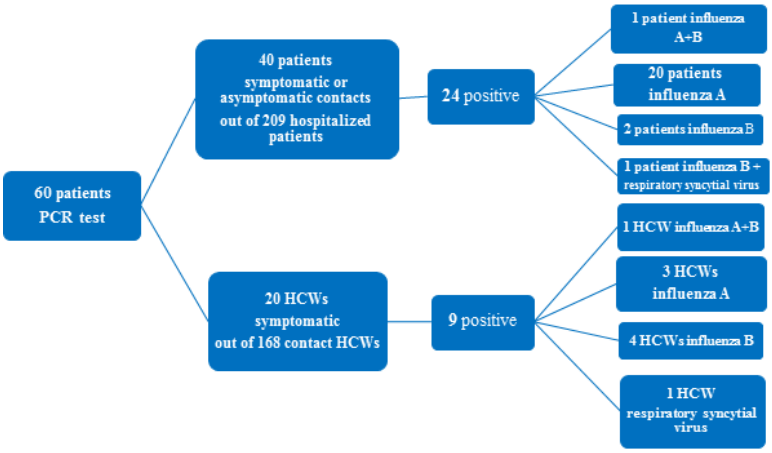

Fig. 1. Distribution of PCR tested cases

In the next 2 days we tested and diagnosed 3 other ICU influenza A H_1N_1 cases using remote (out-of-hospital) assays. The virus strain detection was performed only in the first four cases. Giving the epidemiological context, we considered the following detected influenza A viruses having the same subtype.

In response to the four potentially linked cases, an outbreak was declared. The epidemiological alert was upgraded, visitors' and students' access was denied, daily clinical examination of patients and HCWs for respiratory symptoms was performed, isolation of influenza patients and contacts were instituted, HCWs' appropriate hand hygiene and wearing surgical face masks all the time all over the hospital were mandatory. HCWs with symptoms were advised to stay off work until fully recovered. On the same time the hospital purchased rapid PCR tests for influenza detection and antiviral treatment (oseltamivir) in sufficient proactive supply. Oseltamivir treat-

ment was rapidly instituted in all symptomatic patients and HCWs and in asymptomatic high-risk immune-compromised contacts. The institution vaccination lists were checked and unvaccinated, asymptomatic HCWs received influenza vaccine. Hospital admission of patients scheduled for elective treatments or surgery were postponed.

The peak of newly diagnosed influenza A cases per day was on the 2nd of February 2018 (8 cases). The last influenza case was diagnosed one month after, on the 23rd of February 2018 (fig. 2).

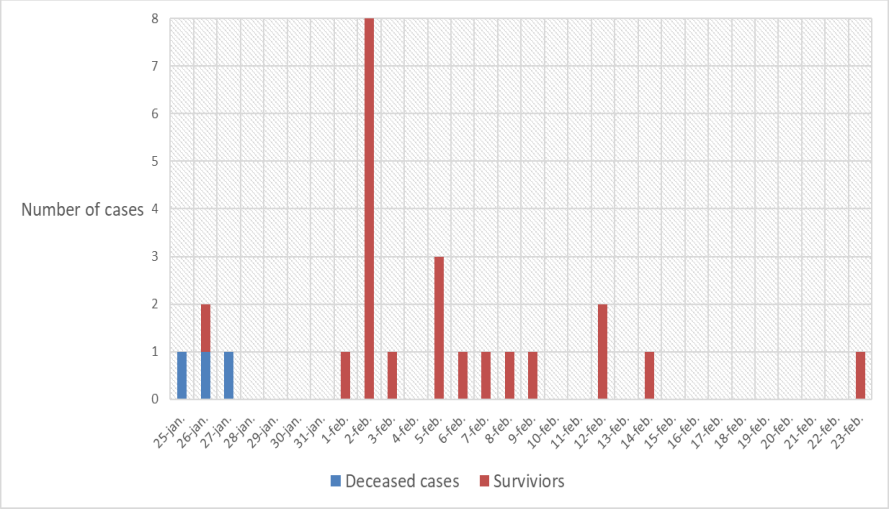

Fig. 2. Temporal dynamics of newly diagnosed influenza A cases and their influenza-related outcome

None of the infected patients and only 1 infected HCW had been previously immunized with the seasonal influenza vaccine.

A total of 9 patients with hospital-acquired influenza A were managed in the ICU, including the first case that was diagnosed: 5 patients for severe and 4 patients for mild/moderate ARDS (fig. 3).

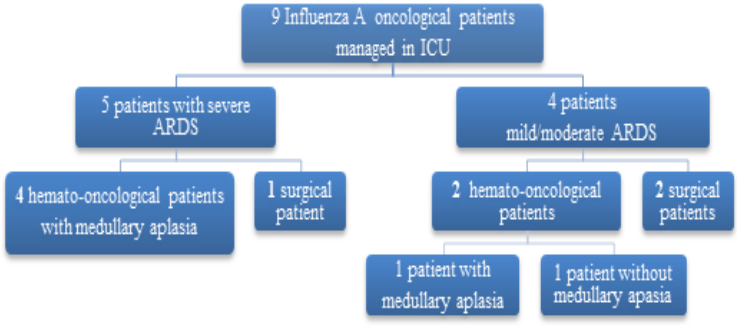

Fig. 3. Patients diagnosed with Influenza A managed in ICU

The patients with severe ARDS were: 4 medical (hemato-oncological) patients with post-chemotherapy medullary aplasia and 1 surgical patient with gynecological surgery. All cases needed ventilatory support: non-invasive ventilation (2 patients, worst PaO_2/FiO_2 54-94 mmHg, survivors) or invasive mechanical ventilation in prone position (3 patients, worst PaO_2/FiO_2 29-46 mmHg, deceased). Extracorporeal membrane oxygenation was not available in our ICU and the number of concomitant cases exceeded the capacity of available machines throughout the country. All ICU influenza patients and contacts were strictly isolated, had dedicated vaccinated HCWs wearing protective equipment and received oseltamivir treatment for prolonged periods until virus clearance or death. Mean duration of hospital oseltamivir treatment in survivors was 15.2 (10-21) days. Median ICU length-of-stay (LOS) was 13 (3-24) days in non-survivors and 15 (7-22) days in survivors. The 4 hemato-oncological patients with medullary aplasia had severe ARDS managed with non-invasive (1 patient survivor) or invasive mechanical ventilation (3 patients, non-survivors). All had the resolution of medullary aplasia during ICU stay. One single non-survivor had positive broncho-alveolar lavage cultures with *Pseudomonas aeruginosa* after 23 days of mechanical ventilation in prone position.

We performed PCR testing for virus clearance after resolution of respiratory symptoms. 3 patients out of 6 survivors had positive PCR when discharged from ICU and continued oseltamivir treatment until clearance.

The mortality rate of influenza A patients was 23% (3/13 positive symptomatic patients) due to severe intractable hypoxemia. 2 symptomatics (mild respiratory symptoms) contact patients died due to unrelated causes (1 patient due to septic shock and multiple organ dysfunction, peritonitis by ileal perforation post oncologic surgery for invasive synchronous colon neoplasm; 1 due to hemorrhagic shock in the context of myelo-monocitary chronic leukemia).

DISCUSSION

We describe the course of a hospital-acquired influenza A H_1N_1 infection outbreak in a group of immunocompromised patients in the Regional Institute of Oncology from Iași, Romania. Immunocompromised patients frequently develop neutropenic fever and are at risk of infection with almost any known pathogen, so the diagnosis of influenza infection can be difficult.

It is important to stress that at that time there was no outbreak of influenza in the general population and the rapid PCR diagnostic test was not available. It is very likely a single patient was the origin for influenza outbreak because screening test positive patients were from the same ward or wards who shared the same floor. Patients were housed in 2-4 beds wards and walked within the floor, increasing the opportunity to transmit infection. The clustering of initial cases suggests the Hemato-oncology Department as the source of outbreak and responsible for the secondary spread to the Surgery Department, with which it shares the same floor. As in the study of Drozd-Sokolowska *et al.* we could not establish the exact origin of infection: a patient could have been infected symptomatically or asymptomatically prior to admission and developed the disease (as a result of immunodeficiency or after chemo / radiotherapy) or could have been infected by an asymptomatic infected patient or HCW (4). The first 4 cases were diagnosed

at "Dr. I. Cantacuzino" National Institute in Bucharest, where the type A and subtype H_1N_1 were assessed. The other cases were diagnosed in our institution by PCR test, which detected only influenza virus type. In the epidemiological context we presumed all influenza type A patients had the subtype H_1N_1.Transmission of influenza virus occurs through aerosols, droplets or direct contact with hands and touch points. Patients, visitors and HCWs are usually involved in the transmission chain (9). We had only one influenza A and B infected patient, which was a symptomatic ICU contact patient, treated for influenza A with complete resolution of respiratory symptoms. Studies show that the co-infection with influenza A and B does not have a worse prognostic than mono-infection, this concomitant infection being mainly nosocomial (10).

Souza *et al.* showed that the median duration of viral shedding in a population of influenza A H_1N_1 infected cancer patients receiving immunosuppression was 23 days, with a range between 11-63 days (11). Among hospital admitted cancer patients with respiratory symptoms during times of an influenza epidemic, 21-33% might test positive for influenza (12). Our hospital hosts immune-compromised patients at high risk of developing severe forms of viral infection. This aspect raises another concern regarding the hospital's availability for rapid diagnosis testing. Could this allow sooner outbreak detection and limitation? At the beginning of outbreak, one deciding factor for spread and outcome was the lack of rapid diagnosis. The out-of-hospital and out-of-city confirmed diagnosis in the first 4 cases lasted 48 hours after suspicion, delaying the initiation of antiviral treatment. The facts that all these patients developed severe ARDS, 3 of them died and the nonsurvivors were only patients with delayed treatment outline the utmost importance of early diagnosis and early antiviral treatment in case of immunocompromised patients with type A influenza. Our conclusion is that influenza rapid diagnostic test should be readily available during the flu season and in hospitals with high risk patients.

After the first case diagnosis, all symptomatic influenza patients and asymptomatic PCR test positive contacts were treated with oseltamivir 150 mg/day. In immunosuppressed patients, antiviral treatment should be administrated independently of symptoms onset, unlike the general population, where its efficiency is questionable after the first 48 hours of symptoms (13). Considering the high incidence of severe forms in influenza infections and the high duration of viral shedding in immunocompromised patients, any oncological hospital should have the antiviral drug available at any time. In these patients, a 48-hour delay in receiving antiviral therapy is associated with an increased risk of developing pneumonia and greater mortality (14), as the case for our first 4 patients. We should also consider that in immunocompromised patients, symptoms are discrete or atypical, so hematologists should stay alert to suspicion of influenza infection, diagnose it early and initiate antiviral treatment without delay.

Complete recovery was considered at resolution of all influenza-related signs and symptoms, independently of the viral shedding (15). PCR retesting was made at complete recovery and before ICU discharge. 3 out of 9 ICU influenza patients were transferred on their wards with a positive PCR test. This raises another issue, concerning the isolation of these patients on their

wards and increased risk of viral transmission due to long viral shedding in immunocompromised patients.

A discussion should be made also concerning the quarantine state and measures implemented for containing and limiting the outbreak. In case of hospitals with patients at risk, as oncological hospitals, we should consider if implementation of quarantine should have been made earlier and when is the adequate moment of lifting this state. Considering that no other influenza A cases were declared at that time in our city, the hospital quarantine was instituted only after the diagnosis of the first case. But soon after, there was a rapid spread of the influenza infection through the whole country, therefore quarantine measures continued even 1 month after the diagnosis of the last case.

Efficacy of influenza vaccination in immunocompromised patients has limited and contradictory evidence. Although the immunogenicity of influenza vaccine is overall reduced, there is a trend of impaired humoral vaccine response in these patients. Despite the fact that the same immune dysfunction, that increases the risk and consequences of influenza infection might also compromise vaccine response and effectiveness, current evidence favor vaccination (8). But, despite this recommendation, rates of influenza vaccination remain low in general population and in cancer patients worldwide due to controversy regarding its effectiveness and safety and lack of physician's prescription. None of our influenza positive patients and just one of infected HCWs were previously vaccinated for seasonal flu. 2 review articles recommend vaccination every year, timed at more than 2 weeks before receiving chemotherapy or between chemotherapy cycles (16, 17). As a result of this outbreak and according to the latest guidelines for vaccination of the immunocompromised host (18), we intend to recommend vaccination as a standard policy to be implemented in our hospital for all immunocompromised patients and exposed HCWs during the season flu.

CONCLUSIONS

We describe the course of a hospital-acquired influenza A H_1N_1 infection outbreak in a group of immunocompromised oncological patients. Immunocompromised patients frequently develop neutropenic fever and are at risk of infection with almost any known pathogen, thus the diagnosis of influenza infection can be difficult. During the flu season and even out of epidemiological context suspicion of influenza infection should be considered in immunocompromised patients with respiratory symptoms. Rapid diagnostic tests and antiviral therapy should be available. Early diagnosis and early institution of treatment are determinants of influenza-related outcome. Epidemiological measures should be implemented in order to avoid and control the spread of infection within a highly predisposed community: the hospitalized immunocompromised patients.

EARLY ENDOSCOPIC PHOTODYNAMIC DIAGNOSIS OF COLONIC LESIONS. (Abstract) **Aim:** The aim of the study is to improve the quality of early endoscopic verification of aplastic changes of the colonic mucosa by use of the photodynamic diagnosis method. **Material and methods:** The study is based on 2,817 video colonoscopies; bioptates were taken in 1,206 cases, representing 43% of the total number of endoscopic examinations. In 72 patients (44 males and 28 female) with neoplasia of the colon videocolonoscopic examination using the photodynamic diagnostics method was performed. **Results:** The results of endoscopic examination using the method of photodynamic diagnosis of 72 patients (44 male and 28 female) with neoplasia of the colon are presented. The method of photodynamic diagnostics is based on the differences of the autofluorescence spectra, which is characteristic for the unchanged mucous membrane of the colon (λ_{max}= 535-565 nm) and induced by the photosensitizer of fluorescence of morphologically atypical cells (λ_{max}=595-640 nm). **Conclusions:** The use of photodynamic diagnostics allowed to increase the accuracy, sensitivity and specificity of neoplastic processes of the colonic mucosa verification to 97.1%, 94.9% and 94.2%, accordingly, and the frequency of coincidence of endoscopic and pathohistological diagnoses 95.2%. Keywords: COLON, CANCER, NEOPLASM, DIAGNOSIS, ENDOSCOPY.

About 600,000 new cases of colorectal cancer are registered worldwide annually. In the general structure of all malignancies, the colorectal cancer possesses the fourth place in terms of morbidity and mortality with the average incidence (standardized indicator) of 13.0 cases per 100,000 population. Moreover, 44.5% of patients are diagnosed in advanced disease stages. Morphologically, the diagnosis was confirmed in 81.7%, with positive histologic findings in 78.5% of patients. About 20-35% of patients die of colorectal cancer during less than one year (1). The issue of colorectal lesions diagnostics in the early stages of disease remains relevant in modern coloproctology, considering the incidence of colorectal cancer, the presence of complications in treated patients and mortality rates among patients with this pathology (2-4), though screening techniques significantly improved the situation. Endoscopic verification of the pathological process is the "gold standard" in the diagnosis of pre-malignant diseases and malignant neoplasms of the colon (5-7). Only a visual

assessment of pathological changes of the intestinal mucosa in the early stages, even by an experienced endoscopic specialist can`t be considered sufficiently informative considering the minimal or unclear macroscopic changes in the structure of pathologically affected epithelium (8). On the other hand, endoscopic sampling of biopsy material from pathologically affected mucosa just under visual control has similar disadvantages, especially with spread mucosal processes (9). This is because, quite often, neoplastic cells have a small and multifocal mosaic type of localization within the pathologic area of the mucosa detected by endoscopist (9).

Mentioned above stimulates clinicians and researchers to find possible ways and techniques that make it possible to increase the recognition value of endoscopic diagnostics of precancerous diseases and malignant neoplasms of the colon in the early stages of development of the pathological process (2). Use of new physical approaches like laser-confocal endoscopy or chromoendoscopic techniques opens new horizons in colorectal diagnostics (10). Among them, use of fluorescent media for colorectal endoscopies is one of the promising.

The aim of the study is to improve the quality of early endoscopic verification of aplastic changes of the colonic mucosa by the use of the photodynamic diagnostics method.

MATERIAL AND METHODS

In total, 2817 video colonoscopies were performed during 2016-2019. Bioptates were taken in 1,206 cases, representing 43% of the total number of endoscopic examinations. In 72 patients (44 males and 28 female) with neoplasia of the colon videocolonoscopic examination using the photodynamic diagnostics method was performed. The mean age of the patients was 59.3±10.2 years. According to The Paris endoscopic classification of superficial neoplastic lesions: esophagus, stomach and colon (11), 11 patients (15%) had a 0-Is type of neoplasia, 18 (25%) had 0-Ip, in 16 patients (22%) – 0-Isp. Non- polypoid neoplasms of type 0-IIa took place in 6 patients (8%), 0-IIb – in 2 (3%). LST-G (0-IIa+Is) neoplasms were diagnosed in 2 patients (3%), LST-NG (0-IIa) in 3 (4%). Type I polypoid cancers were found in 14 patients (20%).

The method of photodynamic diagnostics (FDD) is based on the differences of the autofluorescence spectra, which are characteristic for the unaltered colonic mucosa (λ_{max}=535-565 nm) (fig. 1) and the induced fluorescence of morphologically atypical cells with photosensitizer (λ_{max}=595-640 nm) (fig. 2).

For the photodynamic diagnostics we used the fluorescence diagnostics system SFD.M16-1S.2 manufactured by the Ukrainian National Technical University and the photosensitizer medium hypericin.

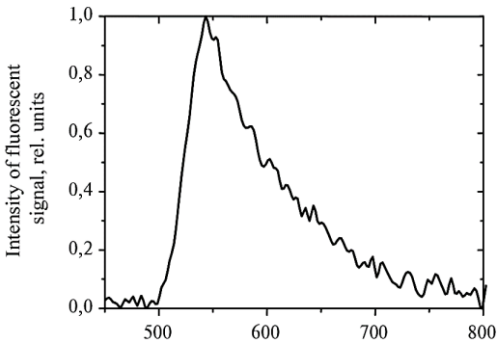

Fig. 1. Diagram of the fluorescence spectrum of the normal colonic mucosa.

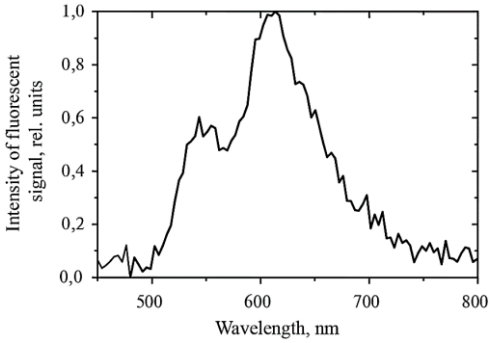

Fig. 2. Diagram of the fluorescence spectrum of the morphologically atypical cells.

The advantages of use of the photosensitizing medium are as follows:

- Oral administration of photosensitizer.
- Colonoscopy within 8-12 hours after the administration of the drug.
- The biological half-life of the drug is about 24 hours.
- The absence of the need for "shadow exposure" of the patient (staying in a darkened room) in the period after receiving a photosensitizer, that allows performing of examination in an outpatient conditions.

The advantages of use of fluorescent diagnostics system SFD.M16-1S.2 are:

- Optical radiation supply, excitation of fluorescence and collection of fluorescent signal through standard optical fibers that are compatible with the instrumental channel of serial endoscopes.
- The registration period of the fluorescence spectrum from the study area does not exceed 1-2 seconds, that does not fundamentally affect the total duration of traditional endoscopic examination.

Endoscopic examination was performed within 8-12 hours after patients receive two capsules of 8 mg hypericin. Its pharmacological action is based on the photosensitizing properties of hypericin, which selectively accumulate only in the dysplastic, metaplastic and tumor cells of the gastrointestinal mucosa and are retained in them during 4-12 hours after ingestion of the drug (2). During the video colonoscopy, the nature of the suspected pathologically affected mucosal area was visually assessed. From areas that had photosensitizer-induced fluorescence characteristics for morphologically affected cells biopsy material was taken.

For comparison, three groups of patients, comparative by age and nature of pathological changes of the colonic mucosa, whose biopsy material was collected only on the basis of visual assessment of the nature of pathological changes (28 patients), using the method of chromoendoscopy with indigocarmin solution (23 patients), and for assessment of neoplastic changes` nature in the colonic mucosa by narrow band imaging (NBI) video colonoscopy 32 patients were involved into the study.

In all cases, the final verification of neoplastic changes in the biopsy material of the colonic mucosa was performed by certified pathologist. Evaluation of the results of the study was made by comparing the data of the visual and morphological nature of pathological changes, namely the presence of dysplasia of different severity, metaplasia or malignant cells in biopsy material, obtained in the researched and control groups of patients, and calculation of statistical indicators, as sensitivity, specificity and accuracy of appropriate diagnostic methods.

RESULTS

The nature of pathology presented in patients of comparison groups is shown in first table. Analyzing the findings, it should

be noted, that endoscopic diagnostic techniques based on the use of a chromoendoscopy or NBI mode colonoscopy have a fundamental disadvantage of dependence of the result, as with conventional endoscopy, on the experience and professionalism of the physician performing the endoscopic examination.

TABLE I

The nature of neoplastic changes of the colonic mucosa in studied patients

Type of neoplasia	Colonoscopy, standard	Colonoscopy with chromoendoscopy	Colonoscopy in NBI mode	Colonoscopy with FDD	Total
0-Is	3 (11%)	3 (13%)	3 (9%)	11 (15%)	20 (13%)
0-Ip	5 (18%)	2 (9%)	6 (19%)	18 (25%)	31 (20%)
0-Isp	7 (25%)	4 (17%)	5 (16%)	16 (22%)	32 (21%)
0-IIa	2 (7%)	2 (9%)	4 (13%)	6 (8%)	14 (9%)
0-IIb	2 (7%)	2 (9%)	2 (6%)	2 (3%)	8 (5%)
LST-G	2 (7%)	1 (4%)	2 (6%)	2 (3%)	7 (4%)
LST-NG	0 (0%)	1 (4%)	1 (3%)	3 (4%)	5 (3%)
Cancer I	7 (25%)	8 (35%)	9 (28%)	14 (20%)	38 (25%)
Total	28 (100%)	23 (100%)	32 (100%)	72 (100%)	155 (100%)

In contrast, the method of photodynamic diagnostics enables real-time differentiation of the unchanged and pathologically affected areas of the gastrointestinal mucosa more objectively, and, accordingly, to detect neoplastic processes on the early stages reliably and in time, with the decision of further treatment. In this case, the degree of dysplastic changes of tumor has a direct dependence on the intensity of the fluorescent signal from the pathological area, which may be an additional factor in verifying the focus with the maximal pathological changes in the mucosa.

The statistics obtained during the study is shown in second table.

TABLE II

Comparative characteristics of methods for early diagnostics of aplastic processes in colon

Variable	Colonoscopy, standard	Colonoscopy with chromoendoscopy	Colonoscopy in NBI mode	Colonoscopy with FDD
Accuracy	71.4%	87.5%	93.7%	97.1%
Sensitivity	72.1%	89.7%	90.6%	94.9%
Specificity	65.7%	81.3%	83.7%	94.2%
Frequency of endoscopic and histological data congruence	68.5%	83.4%	87.3%	95.2%

DISCUSSION

Early diagnosis of colonic lesion is an important, though difficult issue (2, 3). This study shows benefits of the endoscopic photodynamic diagnostics of colonic lesions. While this method shows multiple benefits compared to standard endoscopy of confocal endomicroscopy (9), several short comes and limitations were revealed, similar to previously published papers (5, 10). Among the disadvantages of the photodynamic diagnostics method revealed during the study are the possibilities of influencing the quality of the fluorescence signal of the blood in the lumen of the intestine and the influence on the intensity and quality of the signal at a distance from the mucosa at which the fiber is located. The latter should be not more than within a few millimeters.

The technique of photodynamic diagnostics made it possible, during endoscopic examination in real time, to collect biopsy material precisely from focuses in which dysplastic, metaplastic or malignant cells are localized, even in the mosaic location within the pathological focus of the colonic mucosa for the further pathohistological examination of biopsies. The results indicate that photodynamic diagnostics can be considered as a highly informative screening method for early verification of neoplastic changes of the colonic mucosa.

CONCLUSIONS

The use of proposed photodynamic diagnostics allows to increase the accuracy, sensitivity and specificity of verification of neoplastic processes of the colonic mucosa to 97.1%, 94.9% and 94.2%, respectively. Photodynamic diagnostics is a modern, highly informative screening method of early endoscopic detection of aplastic colonic processes with the frequency of coincidence of endoscopic and pathohistological diagnoses 95.2%.

NEWS

PEOPLE WITH PRE-EXISTING MENTAL HEALTH DISORDERS DURING THE COVID-19 PANDEMIC

Because of their life circumstances, people with pre-existing mental health disorders might have a higher risk of SARS-CoV-2 infection than those without mental health disorders. Risk factors for infection with SARS-CoV-2 and a severe course of COVID-19 include severe mental illness, alcohol or drug misuse, and homelessness, all of which are associated with other risk factors such as comorbid physical conditions. People with mental disorders are at increased risk of infections in general (and thereby potentially at increased risk of COVID-19) and are more likely to develop severe organ dysfunction and to die in ICUs than people without mental disorders. SARS-CoV-2 might also cause dysregulation of the stress system, which could contribute to the development or exacerbation of psychiatric disorders. Elderly people are at especially high risk of severe COVID-19 illness and mental-health-related consequences because they might already have some cognitive decline. Institutions can become epicenters for infection. Physical distancing can be challenging in these contexts, either because the nature of patients' conditions makes it difficult to manage (e.g., people with learning disabilities) or because of overcrowding (e.g., prisons). Increased death rates in assisted living facilities have been reported worldwide, especially among older people and people with learning disabilities. People with pre-existing mental health disorders have reported increased symptoms and poorer access to services and supports since the onset of the COVID-19 pandemic. Early discharge from psychiatric units and disruption of face-to-face psychiatric care have become common, the negative consequences of which could include relapse, suicidal behavior, lack of access to medical care, and social isolation. Quarantine and lockdown might particularly affect people with pre-existing mental health problems: increased symptoms of anxiety and depression, and high rates of post-traumatic stress disorder and insomnia have been reported (Moreno C, Wykes T, Galderisi S, *et al.* How Mental Health Care should change as a Consequence of the COVID-19 pandemic. *The Lancet Psychiatry* 2020; 7(9): P813-824).

SURGERY IN MESOPOTAMIA, EGYPT, AND CHINA

SURGERY IN MESOPOTAMIA, EGYPT, AND CHINA (Abstract): The science of medicine has recorded a continuous evolution from the very beginning of its existence. In Mesopotamia, the health of the individuals was at the mercy of gods, and treatment was in close relation to astrology. Specialist have managed to retrieve a multitude of medical prescriptions and treatment techniques for various diseases, but no specific discovery has been made related to surgery. China practiced medicine focusing on the prevention of certain diseases, not on treating them. The best-known Chinese surgeon of the ancient era was Hua Tuo. His notoriety was conferred by the fact that he was the first Chinese physician to have used anesthesia during a surgical intervention. The Egyptian people left to posterity numerous papyri full of wise teachings and treatments for a multitude of diseases. The most interesting papyri in London is the one discovered in 1862, focusing on the topic of surgery. The science of medicine has recorded a continuous evolution from the very beginning of its existence. Each civilization has left us a heritage of a wealth of teachings, which led to medicine to be what it is today. It is impossible to establish who had the greatest contribution to the improvement of medical techniques, but it is especially important to use every research undertaken by ancient people. Although most civilizations have used magical techniques to treat the health of individuals, studies have shown that when the situation was serious, people have relied on mixtures of herbs to restore the vitality of our fellow human beings. **Keywords:** SURGERY, MEDICAL TECHNIQUES, ANESTHESIA.

As per the information available nowadays, the first decisive overcoming of the mythical-magical horizon by people involved in the healing craft occurred more or less simultaneously – two or three millennia ago – in several different regions of the Globe: in Greece, in India, and in China. Historians have still been debating passionately where exactly medicine shed its immemorial cloak of superstitions and if – at that far point in the past – certain influences may have been exercised in terms of medical practices and doctrines between the aforementioned areas of civilization (1).

The science of medicine has recorded a continuous evolution from the very beginning of its existence; the art of healing has represented a field of interest from time immemorial. History has shown that – whereas initially the surgical interventions were conducted brutally – as nations progressed, they developed a series of remedies capable of healing the human body. From magic techniques to natural remedies or drugs based on technological science,

the medical sector has been progressing constantly for thousands of years.

Mesopotamia was a territory occupied by modern-day Iraq, a part of western Iran, eastern Syria, and Kuwait; it represents a source of inspiration for the entire ancient world and for nations such as Jews, Egyptians, Persians, Phoenicians, and so on.

From an etymological perspective, the lexeme "Mesopotamia" means "the land between two rivers" and it refers to the well-known rivers Tigris and Euphrates. Specialists have managed to retrieve a multitude of medical prescriptions/recipes and treatment techniques for various diseases, but no specific discovery has been made related to surgery. Whereas some historians have argued that the lack thereof may mean the people in question did not practice such techniques, most experts do not agree with this opinion.

In this territory, medicine in practice had a mainly medical and religious nature (2). The health of the individuals was at the mercy of gods, while treatment was in close relation to astrology. Hammurabi's Code – considered the oldest law collection in the world – comprises a series of regulations for the medical sector. Therefore, should a physician treat a patient's lower limbs, the latter would have to pay five shekels; should the patient be the child of a nobleman, the price lowered to three shekels. Furthermore, concerning the ophthalmological treatments, in case of curing the eyeballs using a tool made of bronze, a physician would charge ten silver shekels. However, the writing included sanctions for practicians, too. In certain situations, a physician risked having their hands cut.

As I have mentioned above, in the Mesopotamian area there were no methods discovered directly attesting the use of surgical techniques, but archaeological finds suggest that it is impossible to deny such a reality. Thus, devices were used that seem to have derived from items normally belonging to a kitchen and made from bronze or wood. In addition, research have reported that the thorns of various trees were used by physicians to stitch the wounds. Bandages were also used at the time; they were even chosen for bone fractures.

Mesopotamian surgery seems to have had a conservative character; however, the outcomes of the procedures remain unknown to this day; there is no information related to anesthesia. Researchers suggest that wine, incense, or myrrh were used to soothe the patients' pain.

Before the year 3000 BC, Egyptian scholars kept the books for businesses, the government, and the society in their hieratical writings on the papyrus (they wrote a multitude a manuscript documents) (3). Under the influence of the Sumerian civilization, the Egyptian people left to posterity numerous papyri full of wise teachings, as well as graphical representations of various medical techniques. Among the best known, we mention here the Ebers Papyrus, the Kahun veterinarian Papyrus, the Kahun Gynecological Papyrus, the Berlin Papyrus, and the London Papyri.

Whereas the Ebers Papyrus has 110 pages and it comprises treatments for a multitude of diseases, one of the most interesting papyri in London is the one discovered by Edwin Smith in 1862, focusing on the topic of surgery. Specialists even consider it the oldest surgery treatise. This historical treasure is considerably different from any other writing discovered thus far. Organized rigorously, it contains a series of researchers mentioned for the first time in the history of mankind.

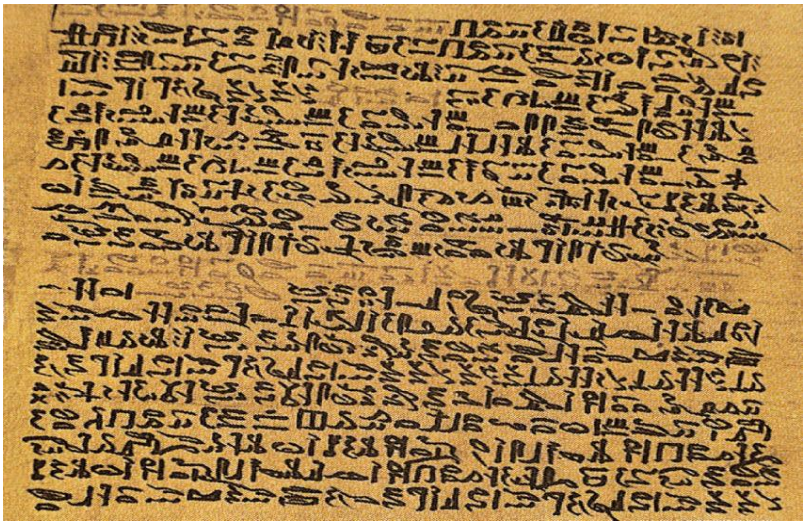

Fig. 1. The Ebers papyrus.
(Photo source: Ellis H, Abdalla S. *A History of Surgery*) (2)

The papyrus is structured on the part of the human body described; hence, the details comprise an individual's head, the chest area, and the spine. Therefore, 48 cases were described in the ancient writing, but only one mentions that the healing process involved magic. The other situations feature issues referring to certain lesions in the head area, to problems with the collarbone and the arms, to blood issues, to sternum, shoulder, or rib problems, and even to issues pertaining to the lower back area.

As for the underlying conversation in order to set a diagnosis, information may also be found among other nations of the ancient civilizations. Thus, it is worth highlighting a physician's triple mission: to assess what had happened in the past (medical history), to inquire about the present issue (current state), and to predict what would happen (prognosis) (4). Concerning the method used for examining a patient according to the Egyptian doctrine, the writing recommends a visual assessment of the person, in order to determine the type of the existing lesion. Surgeons asked various questions and then they told the patient to sit or lie in various positions or they asked the patient to perform certain movements, while the doctor assessed them both visually and olfactory, using various palpation techniques. Depending on the results of the aforementioned examination, the diagnosis fell into three categories. Hence, the first of them concerned the treatable problems; the second included diseases that a patient had "to fight"; the third comprised potentially incurable diseases, case in which the physician was exempted from any responsibility should death occur, given the seriousness of the situation.

The Egyptian era is one of the most interesting phases of universal medicine development and it was seminal in the enrichment of health and illness knowledge. Egyptians had a remarkable medical life, comprising various types of practices; they even had medical specialists and physicians with specific specialties.

Multiple sources attest to the existence of specialists in ophthalmology, dentistry, head problems, or even abdominal disorders, etc. (5).

The Chinese people are renowned for a wide array of scientific inventions that revolutionized the world. In this territory, Shen Nung developed agriculture, while Huangt Ti invented the ships, the bow and the arrows, music, and writing. The art of fishing and hunting was created by Fu Shi, while Yao and Shun outlined the calendar and the administration. Unlike other ancient civilizations, China practiced medicine focusing on the prevention of certain diseases, not on treating them. The first references strictly related to the field of surgery in this territory concern the Chou Dynasty, featuring treatments for swollen wounds, ulcers, and other diseases - traditional Chinese medicine books are known generically as Yijing (6).

The best-known Chinese surgeon of the ancient era was Hua Tuo. He penned several medical texts, and he was sent to prison by the emperor; his writings were entrusted to the prison guard. Unfortunately, they were burned when the famous physician died; his interventions were featured in various works written in that period. Besides the numerous patients healed, his notoriety was conferred by the fact that he was the first Chinese physician to have used anesthesia during a surgical intervention. It comprised a "tingling" powder combined with wine, which enabled the physician to operate on an individual and to remove the affected organs. Among his interventions, it is worth noting removing the liver, the spleen, or the intestines, as well as acupuncture or venesection procedures. His best-known procedures include the one on General Kuan Kung, who adamantly refused to be anesthetized. He had been hit by a poisoned arrow; when Hua Tuo arrived, he was playing chess and he continued the game while the physician was extracting the arrow and cleaning the wound (7).

As for his medical skills, legend says that Hua Tuo received the secrets of this art from two persons; he was advised not to ever discriminate between the rich and the poor, the young or the old, the lower or the higher social ranks (7).

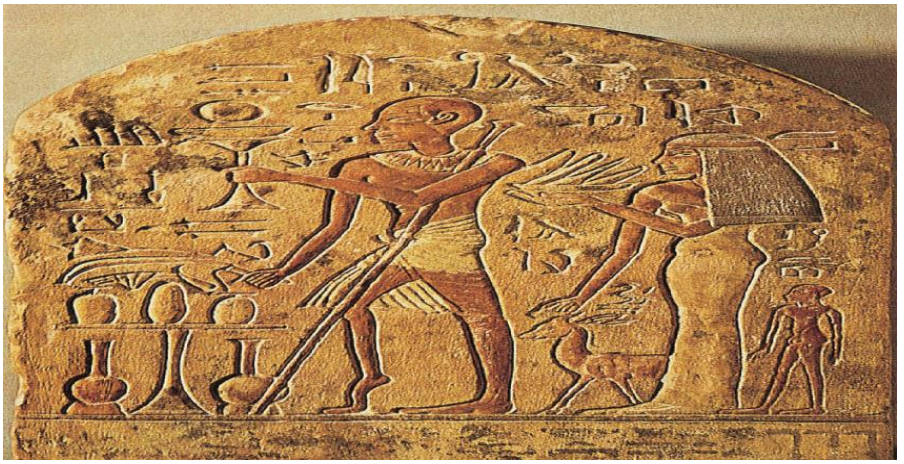

Fig. 2. An Ancient Egyptian stone relief showing a patient with obvious poliomyelitis. (Photo Source: Ellis H, Abdalla S. *A History of Surgery*) (2)

Medicine was closely connected to other fields; hence, philosophy helped people cure their illnesses without external interventions; human suffering was the source of inspiration for a rich argumentative material and even for valuable methodological suggestions (8). Each ancient civilization played an essential role in the development of the modern-day medical sector; it is thus impossible to determine who brought the most important contributions to this field. Nonetheless, certain historians argue that – whereas the Mesopotamians, Egyptians, and Chinese brought significant progresses – other civilizations, such as the Greek civilization, drew mainly on intuition, thus never managing to reach the phase of quantifying the phenomena they studied and to verify empirically the laws they managed to formulate (9). Due to the peoples who left us the legacy of numerous medical procedures, the progress recorded by modern surgery has been possible – is based on such ancient writings, abundant in useful teachings. Most of the times, the rapid pace of technology in our days makes us forget about the existence of the underlying principles in the art of healing. Without these principles, the science of medicine would have never made such tremendous progress.

CONCLUSIONS

The science of medicine has recorded a continuous evolution from the very beginning of its existence.

In Mesopotamia, the health of the individuals was at the mercy of Gods, and treatment was in close relation to astrology. Specialists have managed to retrieve a multitude of medical prescriptions and treatment techniques for various diseases, but no specific discovery has been made related to surgery.

In China medicine was practiced focusing on the prevention of certain diseases, not on treating them. The best-known Chinese surgeon of the ancient era was Hua Tuo. His notoriety was conferred by the fact that he was the first Chinese physician who had used anesthesia during a surgical intervention.

The Egyptian people left to posterity numerous papyri, full of wise teachings and treatments for a multitude of diseases. The most interesting papyri in London is that one discovered in 1862, focusing on the topic of surgery.

150 YEARS SINCE THE BIRTH OF ERNEST JUVARA (1870-1933) (Abstract): Ernest Juvara was born in 1870, in Bârlad, Romania in a wealthy farmer family. He displayed some remarkable aptitudes and skills from early childhood. He finished his primary and high school studies at some of the most famous education institutions in Romania. In 1888 he is accepted at the Paris Medical School. There, Prof. Paul Poirier was an exceptional mentor for Juvara. From him, he learned the art of anatomic drawing. In 1895, Juvara defends his doctoral thesis in medicine and surgery and is awarded *"extrêmement bien"* by the Paris Medical School. In the same year he returns to Romania with Prof. Thoma Ionescu and begins his surgical and university career. During his stay in Paris, he managed to publish a successful anatomy book, personally decorated with multiple original anatomical drawings, and drew over 100 anatomy illustrations for demonstrations and anatomy treatise published by his mentor. His extraordinary surgical and scientific activity, organizer and inventor talent advanced him to the position of tenure professor at only 29 years of age. He is regarded as the founder of the Department of clinical surgery at Iași Faculty of Medicine and one of the orthopedics pioneers in Romania. Throughout his career he drew over 3,000 original anatomy illustrations and published over 230 articles and books. We pay tribute to one of the pillars of Romanian medicine, Ernest Juvara, a skillful surgeon, a talented professor, artist, and inventor, and especially a truly remarkable personality. **Keywords:** ERNEST JUVARA, HISTORY OF MEDICINE, ORTHOPEDICS, ROMANIAN MEDICINE.

Childhood and education

Ernest Juvara (fig. 1) was born on May 14th, 1870, in Bârlad, Romania. His father, Iorgu Juvara, was a wealthy farmer. During his childhood he was very shy, but this personality trait eventually worked in his

favor. His isolation from other children pushed him towards some remarkable activities for his age. One of his teachers, Professor Socrate Lalu, told the story of how Juvara completely disassembled and reassembled the first mechanical watch he received from his parents. The watch worked without an issue.

Aware of the remarkable aptitudes and skills he developed from early childhood, his parents sent him to the Romanian capital, Bucharest. Here he finished his primary school studies at "Urechia" Institute. He graduated from high-school at "Saint Sava" College – one of the most famous high-schools in Romania (fig. 2). According to the only 1880-1888 class book to survive the German bombardment of Bucharest in 1944, Juvara was not at the top of his class. Still, his physics and chemistry professor acknowledged his interest in applied sciences. In 1886, while still in high-school, Ernest Juvara was named laboratory preparer.

(1)

Fig. 2. "Saint Sava" National College, Bucharest (left) – founded in 1694 by Wallachian Prince and martyr, Constantin Brancoveanu (1654-1714) (right)

Student at the Paris Medical School

In 1888 he received his baccalaureate diploma in literature and sciences. In the same year, he is accepted at the Medical School in Paris. In that period, anatomy was taught by Prof. Louis Hubert Farabeuf (1841 – 1910). He often used drawings and chalkboard sketches, which inspired young Ernest Juvara to make use of his natural talent for drawing. At first, he tried to imitate his mentor and later even surpassed him. While the drawings were Prof. Farabeuf specialty, the practical demonstrations were Prof. Paul Poirier`s responsibility.

Even though, Juvara was learning from some of the best professors at the Paris Medical School, his appetite for scientific knowledge was not satisfied. He arranged a laboratory in his own home, where he continued his studies of anatomy, chemistry, and botany. At the same time, his chemistry professor, Armand Gauthier (1837-1920) offered him the position of laboratory preparer for three years (1890-1892).

Still, anatomy was his utmost passion. He was the favorite student of Prof. Paul Poirier (1853-1907) (fig. 3) who noticed his earnestness, dexterity in dissections and especially talent for anatomical drawing.

Prof. Poirier was a remarkable teacher who maintained an atmosphere of friendship in his laboratory. He often invited his students to bicycle and automobile races. This was the catalyst for Juvara who in later years was one of the first automobile owners in Romania. He remained for 5 years in Prof. Poirier`s laboratory where he met some of the greatest minds of the last century. This was a crucial decision for Juvara, who managed to meet here some of the most prominent Romanian doctors such as Thoma Ionescu (fig. 4) and Ion Cantacuzino (fig. 5).

Fig. 3. Paul Poirier c. 1893

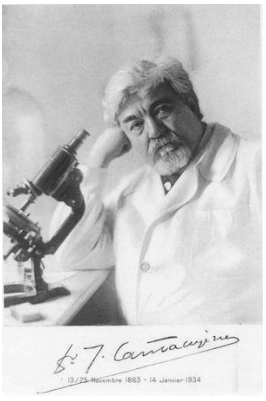

Fig. 5. Ion Cantacuzino (1863-1934)
Image is in the public domain

Passionate about the study and teaching of anatomy, in 1892, Juvara decided to write together with H. Friteau *"Quinze leçons d'anatomie pratique" (Eng. Fifty lessons of practical anatomy)*. This book contained 84 original drawings and sketches handcrafted by Ernest Juvara. The book was a great success. The two authors published five editions of this book. Later, it was even translated in German and Romanian.

In 1894, Prof. Poirier decided to publish a treatise of human anatomy. In this endeavor, he assigned the digestive tract chapter to Thoma Ionescu and the coordination of the manufacturing of all anatomical drawings to Ernest Juvara. Of his experience in Prof. Poirier's laboratory, Juvara will later write in his memoire:

"In Paris, under the influence of Farabeuf and Poirier and advised by artists such as Cuyer, Leuba, Devy and others, I caught the taste for scientific drawing. As chief of Prof. Poirier`s laboratory, I drew over 100 scientific drawings which still serve today for anatomy demonstrations at the Paris University. Later, I coordinated the manufacturing of the drawings for Poirier's anatomy treaty."

In 1895, Juvara defends his doctoral thesis in medicine and surgery *"Anatomie de la région ptérygo-maxilaire"* who was awarded *"extêmement bien"* by the Paris Medical School. Even before he finished the thesis, he was appointed assistant professor in the surgical clinic of Colțea Hospital in Bucharest and chief of the topographic anatomy laboratory, which was led by Thoma Ionescu. The two doctors were recalled in Romania through a special law in 1895.

Juvara left Paris after 8 years of studies, where he left a lasting impression on all his professors and collaborators. Prof. Poirier often said about him that he never had a more talented student than Juvara.

Return to Romania with Thoma Ionescu

He returns to Romania, together with his mentor, Thoma Ionescu in 1895. Here, Juvara began a double and tireless medical career. One was clinical surgery at Colțea Hospital in Bucharest, where he operated side by side with his mentor and the other as assistant professor at the Institute for Topographic Anatomy and Experimental Surgery where he worked every day from 2 P.M. until the evening.

As subdirector of the institute, Juvara firstly took care of its organization. He chose a new and courageous style for that time. In addition to the surgical clinic, the institute also contained a dedicated unit for research and experimentation, which was also divided in multiple departments: topographic anatomy, comparative anatomy, microscopic anatomy (physiological and pathological), physiology and experimental surgery. While he was occupied with organizing this structure, Thoma Ionescu succeeded in mustering some of the best and enthusiastic Romanian doctors for this new and exciting institute.

In 1897, Juvara publishes "*Lecțiuni de anatomie practică" (Eng. Lessons of practical anatomy)*. It was a follow-up to the successful French version he published in 1892. This book was again a great success in Romania. This motivated him to publish in 1899 a German version which now contained 183 drawings (fig. 6).

Ernest Juvara was always striving for better details in his drawings. In this endeavor, he decided to make use of photography - a new, emerging technology at the time. The first Romanian photo was shot only 50 years before in 1848. His technique

involved the hardening of the tissues using formaldehyde, sectioning, photography, and later drawing. This positioned him in the hall of Romanian pioneers of medical photography art alongside Gheorghe Marinescu (1863-1938).

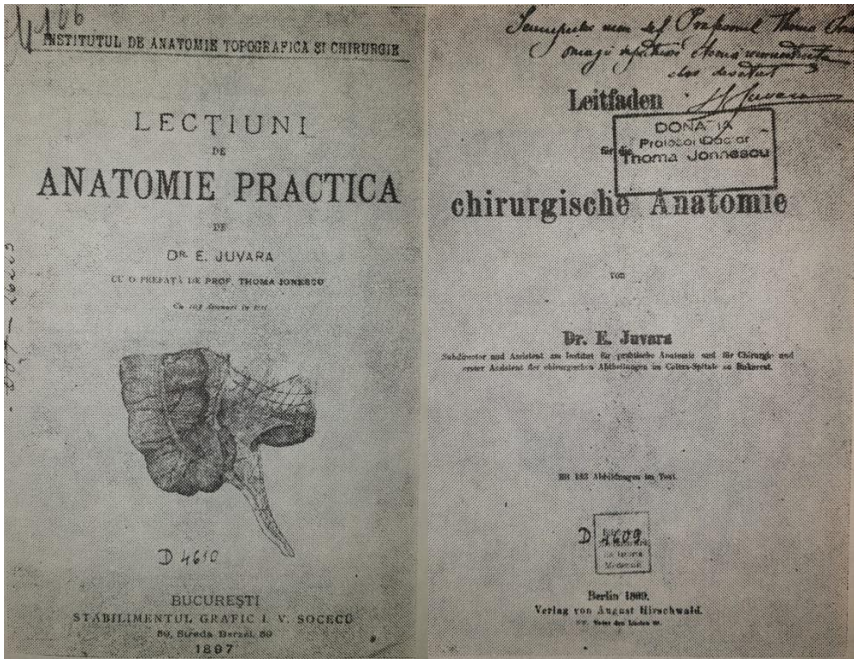

Fig. 6. First page of "*Lecțiuni de anatomie practică"* (Left) and *"Leitfaden fur die chirurgische Anatomie"* (Right)
Image source: Fagarasanu I, *Ernest Juvara omul si opera*, Romanian Academy Publishing House, Bucharest, 1986 (1)

Juvara was an exceptionally talented surgeon, who created numerous procedures. Some of them were considered classic in the international scientific community. In 1897 he published *"Procedeele operatorii contra prolapsului complet al rectului si in particular despre un nou procedeu (Eng. Operative procedures against complete rectal prolapse and in particular a new procedure)"* in *"Revista de Chirurgie"*. Later, this became internationally known as the Juvara or Delorme-Juvara procedure.

He was also a prolific inventor. While under the tutelage of Thoma Ionescu, he invented multiple surgical instruments and sterilizing devices with Collin House and Adnet House in Paris and Lautenschläger House in Berlin (2).

Professor of topographic anatomy and clinical surgery at Iași

At Thoma Ionescu's initiative, Juvara applied to the position of associate professor of topographic anatomy in Iași. After passing the afferent contest, on November 1st, 1899 under Decree nr. 4414 of the Minister of Health, Juvara is named associate professor of topographic anatomy in Iași. His mentor continued to promote him in all university and academic circles. After just

5 years, on November 26th, 1904, Ernest Juvara became tenure professor of topographic anatomy and clinical surgery at Iasi Faculty of Medicine.

Under these circumstances, Juvara became tenure professor at just 29 years and founder of department of clinical surgery at Iași Faculty of Medicine. This was a well-deserved distinction for a man who had a thorough education in those two fields. After all, he was the pupil of Farabeuf and Poirier for 6 years and Thoma Ionescu for another 5 years.

As always, new beginnings are difficult. The new university department did not have an associated surgical department or even a basic laboratory. Even more so, there were no resources for course demonstrations, except cadavers who also were not stored properly.

After a short struggle, two years later, in 1906 a brand-new surgical department was established at "Saint Spyridon" Hospital in Iasi (fig. 7). Initially, only 20 beds were assigned, but it slowly grew in both size and renown. By 1910, the department had over 80 beds and Prof. Juvara performed over 5,800 surgeries.

Fig. 7. Saint Spyridon Hospital, 1845 Drawing by I. Rey *"Album de douze vues de la ville de Iassy"* Image in public domain

In those two years, he was not idle. He took upon himself the task of adorning the new university department with anatomical drawings, each piece individually handcrafted by himself. In 1900 he wrote about those drawings: *"they require a lot of my time, because I have to check them alone side by side with a cadaver and take notes that afterwards need to be scaled to larger dimensions on special paper and color them in order to highlight the most interesting part."*

His strenuous work was admired in 1906 at the National General Exhibition. Later, in 1912, when visiting the Iasi Faculty of Medicine together with King Carol the 1st of Romania, the famous German anatomist, Heinrich von Waldeyer (1836-1921), requested to be left alone to freely admire Juvara's work. This newly founded museum of surgical anatomy also contained numerous photographs of patients before the surgery, as he requested this to be standard procedure with every patient.

As a pupil of Thoma Ionescu, Juvara was the first to introduce rachianesthesia in

Iasi, without excluding the other types of anesthesia. One of his students, Ion Fagarasanu, writes: *"Personally, I have seen no complications or sequelae on the several thousand rachianesthesia performed in ten years, while I was an assistant to Juvara".*

His results were so impressive that one of his assistants, Dr. Alexandru Tzaicu (1883-1958) (fig. 8), decided to self-operate his inguinal hernia using this anesthesia method in 1909. This was the first self-operation in the world. Prof. Juvara assisted him with the rachianesthesia, while Dr. Tzaicu self-operated alone.

The experience was later published in 1911 in *"La presse medicale"* in 1911. He reported no incident, no unpleasant phenomena, or complications. As he personally writes, his motivation was to show that this kind of anesthesia is so *"[...] inoffensive that it can be performed with the patient in a sitting position, while with the cocaine anesthesia, even administered locally, is indicated that the patient must be laying horizontally. I had the conviction that the consciousness, intelligence, and the hand will not be affected by inferior injections. [...] I arranged the operating table in such a fashion that I could remain in a sitting position and have the certainty that I will remain this way no matter how anesthetized I will be".*

Ernest Juvara was the first to impose asepsis methods in Iasi and to highlight the importance of this practice to all his students. His intense clinical, surgical, didactic, and scientific activity catches the attention of the *Society of Physicians and Naturalists from Iasi* who elects him to be president in 1910. His work is recognized even by his French colleagues who appoint him corresponding member of the Paris Society of Surgeons (1911) and the National French Society of Surgery (1928).

Fig. 8. Dr. Alexandru Tzaicu self-operating his inguinal hernia, assisted by Prof. Ernest Juvara, 1909, Iasi, Romania

We list only some of his published work, while he was a professor at Iasi: *"Opération de la hernie inguinale par le procédé de Bassini"* based on a personal experience of 800 cases, *"De la création d'un vagin dans le cas de l'absence congénitale, par dédoublement de l'espace intervéssie-rectum, suivi soit d'autoplastie par manchon cutané", "Emasculation totale", "Pleurotomia cu rezectie de coastă sub lambou", "Evidement du plancher buccal"*, etc. *"Lucrari de terapeutică si clinică chirurgicală (Eng. Works of Clinical Surgery and Therapeutics)"* is his last book published while in Iasi. Grigore T. Popa, his successor, says about the deep admiration both staff and students had for Prof. Juvara *"Juvara made a cult out of being a professor and his students made a cult out of him".* Today, he is considered the founder of the modern school of anatomy and surgery in Iasi (3).

Return to Bucharest and the start of the Great War

In 1912, Ernest Juvara is transferred to Bucharest, at Filantropia Hospital as chief of the Department of Clinical Surgery. This transfer was just in time for the start of the Balkan Wars (October 8th, 1912 - July 18th, 1913). In 1913, he is mobilized by the Romanian Armed Forces in Bulgaria (fig. 9), where he offers his entire experience as organizer in the fight against a ferocious enemy: cholera. For the first time in Romanian history a large scale vaccination campaign is executed. In this endeavor, Juvara was responsible of organizing the hospitals where cholera patients were isolated.

Returned from this campaign, he continues his surgical and scientific activity at Filantropia Hospital. Aware of the imminence of the Great War, he is preoccupied with perfecting the rachianesthesia technique and with developing new surgical treatments of fractures. This motivates him to invent several exceptionally useful orthopedic devices described in his outstanding paper *"Tratamentul operator al fracturilor diafizelor prin metoda fixatorului extern (Eng. Surgical Treatment of Diaphyseal Fractures by External Fixator Method)".*

Fig. 9. Maj. Prof. Dr. Ernest Juvara in the Bulgarian Campaign (1913)
Image source: Fagarasanu I, *Ernest Juvara omul si opera*, Romanian Academy Publishing House, Bucharest, 1986 (1)

The Great War begins in 1914 and Romania joins the forces of Antanta in 1916. The same year, Juvara is mobilized by the Romanian Army under the rank of Major. He is attached to the 4th Evacuation Hospital, which was under the command of the 4th Romanian Army. During the war he was dedicated body and soul to the wounded soldiers. He was later promoted to the rank of colonel (fig. 10).

Col. Dr. C. Giurea recalled *"I saw him during the war... both at Hangu and at Brosteni and Bicaz subsections, which he supervised. Many wounded owed their lives only to the tireless day and night work, peerless abilities, and devotion of Prof. Juvara. I*

often saw him, when his surgical work gave him respite, offering advice and helping with the repair of medical trucks' engines, in order to transport the wounded as soon as possible, inspiring the admiration of the mechanics and the respect of surgeons."

Fig. 10. Col. Prof. Dr. Ernest Juvara (red arrow) at the Red Cross Hospital in Botosani (1917). Image source: Fagarasanu I, *Ernest Juvara omul si opera*, Romanian Academy Publishing House, Bucharest, 1986 (1)

At the end of the war, he returns to "Filantropia" Hospital, where he works until 1923 when he is transferred to "Brâncovenesc" Hospital in Bucharest. At the time, this hospital still existed and was considered the best hospital in Romania.

Here he organized the largest and most modern surgical department in Romania (fig. 11). It included over 120 beds. This clinic was later visited by the famous Prof. A. Hartmann (Paris), Prof. Fred H. Albee (New York).

Fig. 11. Prof. Ernest Juvara (red arrow) and his collaborators in the operating room at "Brâncovenesc" Hospital (1928) Image source: Fagarasanu I, *Ernest Juvara omul si opera*, Romanian Academy Publishing House, Bucharest, 1986 (1)

Published work and distinctions

He continues his work in the laboratory as well. He edited a treatise of surgical anatomy meant to have 4 volumes, but in the end only 2 were published: Volume 1 - "Head and neck" (1924) and Volume 2 – "The limbs" (1925). For this project he created over 250 original color drawings, all individually handcrafted by himself. His work was so impressive, that in 1923 when Prof. Jean Louis Faure visited his clinic proposed to Prof. Juvara to donate all his drawings to the Paris Medical Academy.

After the war, his passion remained the orthopedics, especially osteosynthesis. Of his over 230 published works, more than a third are dedicated to osteoarticular pathology.

His student, Ion Fagarasanu, estimates that Prof. Juvara made over 3,000 anatomical drawings throughout his life, surpassing some of the most renown anatomists. This demonstrates how much time and effort he was prepared to invest in his art.

He was decorated with the Order of the Star of Romania, in the rank of Knight by King Ferdinand I of Romania and was elected President of the Romanian Society of Surgery between 1929-1930.

It is known that he had no love for distinctions and honorary functions. He avoided any initiative for promotions to any high-ranking positions. Even when proposals were spontaneously made from outside, he rejected them vigorously. This explains why he was never a Member of Parliament, dean, or rector of the University. Even the title of President of the Romanian Society of Surgery, of which he was a founding member and its first secretary, was awarded to him contrary to his wishes.

At only 63 years, in full health he suffered a tragic death. On May 5th, 1933, following an accident, he was electrocuted in the bath by the lamp he used to read with.

His work was never forgotten. He left behind a renowned Romanian medical school.

One year after his death, his colleagues created a memorial medal in his honor (fig. 12).

Fig. 12. Prof. Dr. Ernest Juvara memorial medal
Image used with the written agreement of the owner

In 1970, UNESCO celebrated a century since the birth of one the most brilliant medical minds Romania had to offer. Also, today his bust can be seen in bronze in the main hall of "Foișor" Clinical Orthopedic Hospital in Bucharest (fig. 13).

Non-medical interests and hobbies

Ernest Juvara was a founding member of the Romanian Automobile Club (1904). His great memories with Prof. Paul Poirier automobile racing in Paris grew into a real passion for automobiles and mechanical work. He was the first man from Iasi to ever have an automobile. It is even more impressive the fact that he ordered from abroad only the chassis and the engine. Everything else, he handcrafted himself (fig. 14).

He published numerous articles in the Romanian Journal *"Automobilul"* regarding different types of carburetors, often drawing related schematics (fig. 15). His passion for mechanics guided him to be a member of the technical commission of the Romanian Automobile Club.

He was in love with nature. He would often go on hikes or casual drives in the country. This, in combination with his passion for automobiles came in very handy during the Great War. Often, he would recommend shorter, less known routes for the ambulance drivers. Juvara was also a passionate hunter and owned an impressive firearms collection.

MACHINE LEARNING IN FETAL CARDIOLOGY: WHAT TO EXPECT

Fetal echocardiography is used for the evaluation of the fetal heart. Due to increased bias, new technologies have emerged. Machine Learning (ML) is a computer science discipline focused on teaching a computer to perform tasks with a specific goal, without explicitly programing on how to perform it. In a recent review, Garcia-Canadilla et al. focus on the usefulness of ML in fetal cardiology. They cited a systematic review on the interobserver reliability between human and ML interpretation of fetal heart rate tracings, with no improve of the outcomes when ML was used. However, in another cited study, ML was successfully used in predicting fetal growth abnormalities in a cohort of more than 30,000 patients. An intelligent navigation method, FINE, developed by Yeo et al., can automatically obtain different sonographic views of the fetal heart and identify cardiac abnormalities. Concluding, ML for the assessment of the fetal heart can be successfully used for the identification of individuals with similar features, leading to a better standardization of fetal cardiac data, thus providing support for the clinical interpretation and taking a correct treatment decision. (Garcia-Canadilla P, Sanchez-Martinez S, Crispi F, Bijnens B. Machine Learning in Fetal Cardiology: What to Expect. *Fetal Diagn Ther* 2020; 47(5): 363-372)

VALUE OF DE LA TORRE-MONDRAGON PROCEDURE IN THE SURGICAL TREATMENT OF PATIENTS WITH HIRSCHSPRUNG'S DISEASE

VALUE OF DE LA TORRE-MONDRAGON PROCEDURE IN THE SURGICAL TREATMENT OF PATIENTS WITH HIRSCHSPRUNG'S DISEASE (Abstract): Hirschsprung's disease (HD) is a congenital anomaly in which numerous improvements in terms of the level of knowledge and treatment options have been made. Along with modern diagnostic tools, like suction biopsy, a number of new surgical techniques were developed, such as the laparoscopic approach and trans anal endorectal pull-through. **Results:** This paper present our experience with De La Torre-Mondragon procedure, in a retrospective study of 28 HD cases. We focused on the value of rectal biopsy and water-soluble contrast enema as main diagnostic tools, the surgical technical details and the encountered complications - perianal dermatitis (10 cases), acute enterocolitis (14 cases), encopresis (4 cases), functional obstruction due to anastomosis in the transition zone (1 case), and mechanical obstruction (3 cases). **Conclusions:** We conclude that the De La Torre-Mondragon surgical technique is for us the procedure of choice in or common forms of HD. **Keywords:** HIRSCHSPRUNG'S DISEASE, CONGENITAL MEGACOLON, DE LA TORRE - MONDRAGON PROCEDURE.

Hirschsprung's disease (HD) is a congenital malformation affecting 1:5.000 live born infants, characterized by the absence of the ganglion cells in the myenteric and submucosal plexuses of the distal gut of variable length which results in absent peristalsis and chronic functional intestinal obstruction (1).

The advances in understanding the genetic and molecular mechanisms helped us understanding that it is a polymorphic, multifactorial disease with a defined multigenic etiology (2). Perturbation in the proper neural crest cell migration, proliferation, differentiation, survival, or apoptosis can all contribute to a dysfunctional enteric nervous system (3).

Regardless of the technique, the purpose of surgical treatment is the removal of the aganglionic bowel segment while keeping intact the anal sphincter and pull through of the ganglionic bowel with the preservation of fecal continence after surgery, without obstructive symptoms such as abdominal distention and postoperative enterocolitis.

The trans anal endorectal pull-through emerged as a need to evolve towards less invasive, single surgical correction of HD disease. At the same time, the age at the time of diagnosis has gradually decreased and in most cases the aganglionosis in-

volves only the rectosigmoid colon. This technique provides the advantages of a minimal access approach with shorter length of stay, shorter time to full feeding, less pain, and improved cosmesis with excellent outcomes (4).

The aim of this study was to present our experience with the implementation and surgical results in HD patients using the De La Torre-Mondragon technique (transanal endorectal pull-through).

MATERIALS AND METHODS

This is a 12-year retrospective, single surgical team experience. The medical records of 43 consecutive patients diagnosed and treated for HD from 2007 to 2019 were analyzed. The diagnosis was confirmed by submucosal rectal biopsy (either suction rectal biopsy or posterior rectal wall biopsy), histopathological examination revealing the absence of ganglion cells in the submucosal layer, and water-soluble contrast enema for the assessment of the anatomy and length of the aganglionic segment and the location of the transition zone. A total of 28 patients were diagnosed with the rectosigmoid HD and were treated using the one-stage transanal endorectal pull-through. The study was approved by the hospital ethics committee. The selected parameters where gender, age at diagnosis, age at surgery, associated malformations, imaging studies, clinical presentation, operative complications, surgical technique, histopathology report, and follow-up.

RESULTS

The study included patients aged 2 weeks to 5 years at the time of diagnosis. Five patients were operated during the neonatal period and 7 patients as infants. The majority were male (19 patients). No patient had a previous laparotomy. Associated malformations were cardiac malformations (9 patients), Down syndrome (5 patients), cleft lip (1 patient), and autistic spectrum disorder (1 patient).

The presenting symptoms included delayed meconium passage in the first 48 hours after birth (18 patients), abdominal distention and vomiting (11 patients), constipation alternating with episodes of enterocolitis (24 patients), and stooling requiring anal stimulation (5 patients). In 85% of cases, rectal exam showed an empty rectal ampulla with fecal impaction at the fingertip or of explosive evacuation stool on finger withdrawal. All patients were prepared preoperatively with 2-3 days of saline irrigations for emptying the impacted colon. The time between clinical diagnosis and surgery was 1 to 3 weeks.

In all cases, the HD diagnosis was made by submucosal rectal biopsy (suction biopsy in 9 patients) which showed absence of ganglion cells and hypertrophic nerve fibers in the Meissner's plexus with hematoxylin-eosin staining (figs. 1, 2). In 2 cases suction biopsy was not conclusive so it required repeated transrectal biopsy. The decision for endorectal surgical approach was made based on the radiologic appearance of the transition segment in the rectal, sigmoid or distal descending colon region with water soluble contrast enema (fig. 3). Intraoperatively, the selection of the colon level for pull through (fig. 4) was confirmed by frozen section biopsy which must show the presence of ganglion cells and normal size hypertrophic terminal nerves. In two cases intraoperative frozen section biopsy showed persistent transition zone which required further dissection and abdominal access. These patients were excluded from the study.

For surgery, all patients were placed in

dorsal decubitus position. A Lone-Star retractor was used to show the dentate line (fig. 5). Injection of saline/lidocaine/ adrenaline in the submucosa was used for hemostasis and to ease extra mucosal dissection. The mucosal incision was made 1.5 cm above the dentate line. The muscular cuff length was 3 to 5 cm with incision of the posterior wall. The operative time was influenced by age (lower in smaller age), difficulty of submucosal dissection due to the inflammatory process caused by recent enterocolitis, and prior posterior rectal wall biopsy. Oral feeding was resumed from postoperative day 1 with clear fluids and from day 5-7 with semiliquid. Patients were followed-up period 6 months to 5 years.

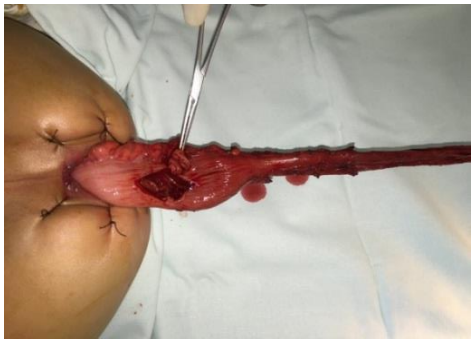

Fig. 4. Total layer biopsy for extemporaneous analysis.

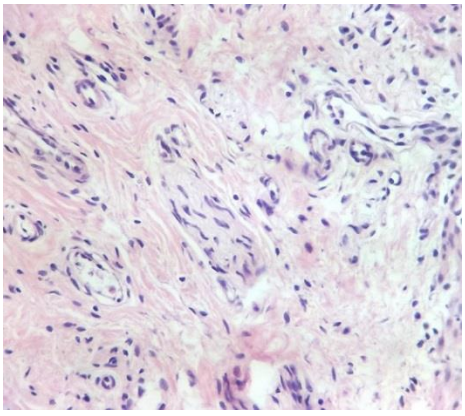

Fig. 2. Absence of ganglionic cells in submucous plexus and nervous fibers hypertrophy.

Fig. 5. Long-Star retractor.

Early postoperative complications included multiple daily soft stools with perianal dermatitis in 10 patients who were not toilet trained yet. The irritation was successfully managed with topical skin barrier products (PVM/MA Copolymers), and the number of daily stools decreased gradually to a normal of 2-3 per day starting with postoperative week 2 or 3. No cases of infection or anastomosis leakage were reported.

Long-distance complication included obstructive symptoms: episodes of acute enterocolitis in 14 cases with a median of 2-5 episodes per year and gradual decrease in the annual follow-up, 1 case of functional obstruction due to anastomosis in the transition zone, and 3 cases of mechanical obstruction (2 cases of stenosis at the anastomosis level and 1 case of stenosis due to the muscular cuff). All parents were taught before and after surgery how to recognize the early signs of enterocolitis and how to do saline irrigations. Only 30% (8 cases) required hospitalization for treatment of postoperative enterocolitis. All 3 cases with mechanical obstruction required redo surgery.

We also had 4 cases of encopresis but no cases of fecal incontinence. The encopresis cases were managed with bowel management: Senna laxatives for a median period of 6 months and hydrosoluble fibers as stool bulking agents. We believe that encopresis occurs in cases where the pull through colon has a degree of dilatation and is not efficient in complete emptying with each bowel movement.

All 6 patients with Down syndrome and autism had a slow postoperative recovery with longer periods of stooling problems of 3 to 6 months (multiple but small daily stools, difficulties in potty training) and more frequent (6-7/year), and severe episodes of acute enterocolitis which required hospitalization.

DISCUSSION

The experience of health professionals in highly specialized tertiary centers in rare congenital and acquired diseases (5,6) is an important factor for a better outcome.

In this study we present our cohort of patients with rectosigmoid HD who underwent one-stage transanal endorectal pull-through in our center. All patients' parents signed a comprehensive informed consent (7).

Complete transanal approach offers the same advantages as laparoscopic-assisted pull-through, namely reduced incidence of postoperative ileus, less postoperative pain, and early hospital discharge. The transanal route has the added advantages of limiting the risk of associated intraabdominal pelvic dissection, such as bleeding, injury to other organs, adhesion formation, better cosmetic results, and reduced cost compared with the laparoscopic-assisted approach and, also, no need for a temporary colic diversion (8, 9, 10). At the same, long-term complications can still occur including anastomotic or muscular cuff stricture, anastomosis of a twisted pull-through, anastomosis in transition zone, enterocolitis, constipation, incontinence, or soiling (11). In most cases, complications are related to the surgical technique and care in following the principles of anal canal dissection.

The age for surgical treatment has been controversial with initial more precaution regarding small age children. In the last years studies have shown that trans anal approach can be successfully and safely used as soon as the diagnosis is made, even in small newborns where the success of the

procedure lies in the magnifying loupes, meticulous dissection, and the fact that the neonatal pelvis is very shallow (4). In the postoperative period, they can develop obstructive symptoms and enterocolitis more frequently, which may be attributed to a functional obstruction caused by the inability of the internal anal sphincter to relax, particularly in not toilet-trained children (12, 13).

Suction biopsy is an easy, safe and efficient way to perform submucosal biopsy at bedside. The main problems are related to the insufficient specimen sample for the evaluation of ganglion cells in the submucosal layer or too close to the dentate line. Previous studies recommended delayed suction biopsy in preterm or low birth neonates, but others (14) showed 100% sensitivity and specificity of suction rectal biopsy for HD in late preterm neonates, small neonates who weighed less than 2,000 g at the time of biopsy including as low as 1,590 g.

Barium enema will show in 80% of HD patients an apparently "normal" size distal bowel with a transition zone and dilated proximal bowel (15). It can be used as a screening test in patients with constipation, but it can give false negative results (16, 17) especially in neonates where the dilated colon is not yet evident or in long segment aganglionosis.

Children with HD and Down syndrome are reported to experience a higher incidence and severity of Hirschsprung-associated enterocolitis. There are several potential factors that may contribute to this: delayed presentation related to the cognitive impairment in these patients which affects the child's ability to effectively communicate symptoms of pain or discomfort in combination with a delayed recognition by the caregiver of child symptoms, such as an episode of enterocolitis. Getting children with Down syndrome to comply with rectal irrigations might be less effective and result in an advanced stage disease at presentation, or the baseline dysfunctional cellular and humoral immune response seen in otherwise healthy patients with Down syndrome without HD may potentiate the infectious disease process in these cases, similar to colitis subsequent to other diseases (18, 19, 20).

Postoperative complications have a common spectrum with other surgical techniques (Soave, Swenson, Duhamel) and vary between different reporting groups (21). They can be grouped into obstructive (functional or mechanical) symptoms and incontinence. Functional obstruction is caused by anastomosis in the transition zone which highlights the need for intraoperative full- thickness frozen biopsy with evaluation of ganglion cells and absence of hypertrophic nerves (22). At the time of surgery, in not toilet-trained patients problems related to efficient anal sphincter relaxation due to retained aganglionic zone at the level of the anal sphincter were noticed, which can be managed with Botox injections (23).

After the surgical intervention, silver dressings can be used to cover the skin lesions in view of preventing bacterial infections (24), but also to reduce pain and accelerate healing (25, 26).

Mechanical obstruction can be caused by twisting the pull-through colon at anastomosis site, anastomotic stricture due to tension suture or poor vascularization, muscular cuff rolling if too long and not split in the posterior wall (27, 28).

In this group of patients, postoperative incontinence should not happen because the sphincter complex in HD patients is integral.

Close dissection with injury of the dentate line or aggressive stretching of the anal canal during surgery should be avoided.

In the long term, prognosis of these patients is very good but with a reported lower quality of life compared with healthy population and better than in those with severe forms (long segment aganglionosis) (29). Postoperative enterocolitis is an inevitable complication and consequently, education of the family is very important in recognizing the early symptoms of acute enterocolitis and performing rectal irrigation. This will avoid the late presentation, severity of symptoms, and the lengthy hospital stay.

CONCLUSIONS

The use of De La Torre-Mondragon surgical technique requires an accurate preoperative diagnosis, both of positive disease and anatomy of the transition zone. It is feasible and safe in young children when following the surgical principles for preserving continence and complete excision of the transition zone. The number of postoperative complications is low, but when they occur, reintervention or long-term care are required. Stooling problems and acute enterocolitis are complications common to all surgical techniques, some are inevitable and thus require family education and proactive measures.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

SUBARACHNOID SPACE WASHOUT METHODS IN ANEURYSMAL SUBARACHNOID HEMORRHAGE (Abstract): Aneurysmal subarachnoid hemorrhage is the most dramatic form of hemorrhagic stroke. This pathology should not be regarded as a single disease, but rather as a set of events that happen in a chain-like manner, with devastating complications and requirement of proper management from the beginning. **Material and methods:** We conducted an observational and retrospective study on a group of 47 patients treated for aneurysmal HSA, with secured aneurysm, over a period of 2 years. **Results:** Patients who underwent surgery within the first 5 days of presentation by external ventricular drainage required shorter hospitalization and had faster social reintegration and better neurorehabilitation. **Conclusions:** The main cause of complications leading to coma or death in patients hospitalized for aneurysmal HSA is symptomatic vasospasm. Various surgical methods are currently used to prevent vasospasm, while others are still under development. We believe that an early approach to the subarachnoid space by opening the cerebrospinal fluid passage is mandatory for a better clinical outcome. **Keywords:** SUBARACHNOID LAVAGE, CEREBROSPINAL FLUID, SYMPTOMATIC VASOSPASM, LUMBAR DRAINAGE, VENTRICULOSTOMY, SUBARACHNOID SPACE WASHOUT.

Subarachnoid hemorrhage occurs as a consequence of a blood vessel rupture in the subarachnoid space or near it. Following this rupture, blood will invade the space between the pia mater and the arachnoid, the subarachnoid space, which normally contains just cerebrospinal fluid. About 85% of all subarachnoid hemorrhage (SAH) forms are due to the rupture of a cerebral aneurysm.

The mortality and morbidity associated with aneurysmal subarachnoid hemorrhage remain at global values of about 40% despite remarkable progress in positive diagnosis and time-efficient management, as well as their accessibility. During hospitalization for this pathology 30-70% of patients suffer a bleeding, and about 90% of them die regardless of the treatment applied.

In the development of cerebral vasospasm, the most devastating complication in terms of prognosis in SAH, hemoglobin degradation products are incriminated. This raises the issue of directly controlling them

by removing or neutralizing them from the subarachnoid space, instead of pathogenic treatment to combat their effects.

PATHOPHYSIOLOGY

The study of cerebrospinal fluid is a key element in the management of aneurysmal subarachnoid hemorrhage. Lumbar puncture is currently the diagnostic method with the highest sensitivity for obtaining a correct positive diagnosis (1, 2). A positive result for aneurysmal SAH consists of increased opening pressure, xanthochromic cerebrospinal fluid (CSF), more than 100,000 red blood cells per mm3, increased proteinuria and low or normal glycorrhea (3, 4).

In 2015 Perry *et al.* stated that the lack of xanthochromia together with erythrocytes < 2,000 x 10^6/L in CSF collected by PL exclude the diagnosis of aneurysmal HSA, the method that has sensitivity of 100% and specificity of 91.2% (4, 5).

The following table compares the characteristics of the CSF in the normal subject *vs.* the one suffering from an SAH.

TABLE I

Comparison of CSF constituents values - normal *vs.* SAH (4, 6, 7)

	Normal	SAH	Commentaries
Color	Colorless	Colorless, xanthochromic, bloody	-
pH	7.33	Increased	
Pressure	70 -180 mm H_2O	Increased in > 60% cases	High proteinorrachia correlates with a worse prognosis
Albuminorachia	< 20 mg/dL	Increased in > 60% cases	-
Proteinorrachia	35 mg/dL	Above normal limit	Increases by approximative 1 mg/dL per 1000 erythrocytes
Glycorrhachia	50 - 80 mg/dL	Normal or decreased	-
Potassium	2.8 mEq/L	Decreased	-
Erythrocytes	Absent	Present	Confusion element – traumatic LP
Bilirubin	Absent	Present	
Nucleate cells	< 3	Increased	Their presence correlates with the amount of hemorrhage

Following the degradation of hemoglobin accumulated in the subarachnoid space, heme and bilirubin are the main constituents formed, these being oxidation products that are deposited around the blood vessels, on which they exert vasoactive, cytotoxic, proteolytic and inflammatory effects. Recent experimental animal studies incriminate these substances as being responsible for the development of vasospasm by inhibiting high-conductance potassium channels of the BKCa type in the smooth muscle fibers of the vascular tunic, secondary to the induction of irreversible cerebral vasoconstriction (8, 9).

As heme is released from hemoglobin, hemoxygenase-1 degrades it into bivalent iron ions, biliverdin and carbon monoxide. Elevated levels of hemoxygenase-1 in choroid plexus cells have been identified in experimental animals with subarachnoid hemorrhage. The increased level of this proteolytic enzyme correlated with a better degree of washing of the subarachnoid

space of Hb degradation products (9, 10).

Increased pH of cerebrospinal fluid has recently been associated in controlled studies with phenomena such as late cerebral ischemia in patients with aneurysmal subarachnoid hemorrhage. This increase in pH is due to the poor clearance of Hb degradation products in the subarachnoid space (11).

The high level of proteinemia does not correlate, according to recent literature, with the risk of developing symptomatic vasospasm, but it seems to be closely linked to a more unfavorable prognosis, based on the disruption of the blood-brain barrier as the incriminating mechanism (7).

MATERIAL AND METHODS

We have analyzed data related to the length of hospitalization and the *Glasgow Outcome Scale* (GOS) score at discharge and return for follow-up control at 3-6 months, in a retrospective and purely observational manner, in patients admitted with aneurysmal subarachnoid hemorrhage for a period of 2 years (2018-2019) in Neurosurgery I Clinic from Bucharest University Emergency Hospital. Results were statistically processed with the application *Minitab.*

Patients with a confirmed diagnosis, with a Fischer grade greater than or equal to 3, who have had the incriminated aneurysm secured by endovascular method or surgical clipping and who required external ventricular drainage during hospitalization (due to intracranial hypertension syndrome or acute hydrocephalus) were included. Deceased patients, patients with complications related to the presence of the drainage device or with significant associated pathology that could act as confounders and could thus parasitize the results were excluded from the study.

Thus, a group of 47 subjects was obtained, homogeneous both in terms of age and in terms of Fischer score at admission. We followed data related to the age and sex of the subjects, the number of days of hospitalization, the time of intervention by external ventricular drainage (in the first 5 days after presentation and after 5 days), Fischer score obtained by brain CT examination at presentation, GOS score at discharge and re-evaluation (3-6 months) depending on the time of ventriculostomy. The examined data were collected from the medical charts and from the electronic archive of the department, and they were processed and included in the second table.

TABLE II

Summary of collected data

Gender	F=18; M=29
Age	Mean = 57 (55 for F, 58 for M)
Fischer score	Mean = 3.468 (3.38 for F, 3.51 for M)
GOS score at discharge	Mean = 4.42 (for 4.68 EVD in the first 5 days, 3.86 for EVD after day 5)
GOS score at 3-6 months	Mean = 4.68 (for 4.71 EVD in the first 5 days, 4.60 for EVD after day 5)
Days of hospital stay	Mean = 16.40 (min = 10, max =31)

The study started from the wish to analyze the impact of mechanical washing of the subarachnoid space in patients with aneurysmal HSA and increased risk of

cerebral vasospasm.

Ventricular drainage performs the mechanical washing of the subarachnoid space. External ventricular drainage involves cannulation of the lateral cerebral ventricle with a ventricular catheter connected to an external drainage device against an adjustable pressure, which is set according to normal intracranial pressure.

Other methods of ensuring mechanical washout of the subarachnoid space are lumbar drainage of the CSF or direct chemical washing with fibrinolytic agents and antioxidants, but these are either controversial or unapproved for current clinical use in Europe.

RESULTS

Among the group of subjects, we obtained (N = 47 subjects) the mean age was 57 years (tab. III), comparable to the data in the literature, which stipulates that SAH mainly affects people in the age range of 55-60 years (12).

TABLE III

Summary of follow-up data related to age and sex

Statistics

Variable	Gender	N	Mean	SE Mean	StDev	Minimum	Q1	Median	Maximum
Age	f	18	55.39	3.46	14.69	23.00	46.75	57.50	81.00
	m	29	58.83	2.04	10.96	31.00	51.50	59.00	79.00

The average Fischer score on admission was 3.468. A homogeneous lot was obtained regarding this score ($p < 0.005$). Data about the Fischer score for this lot of subjects is further characterized in the image below (fig. 1).

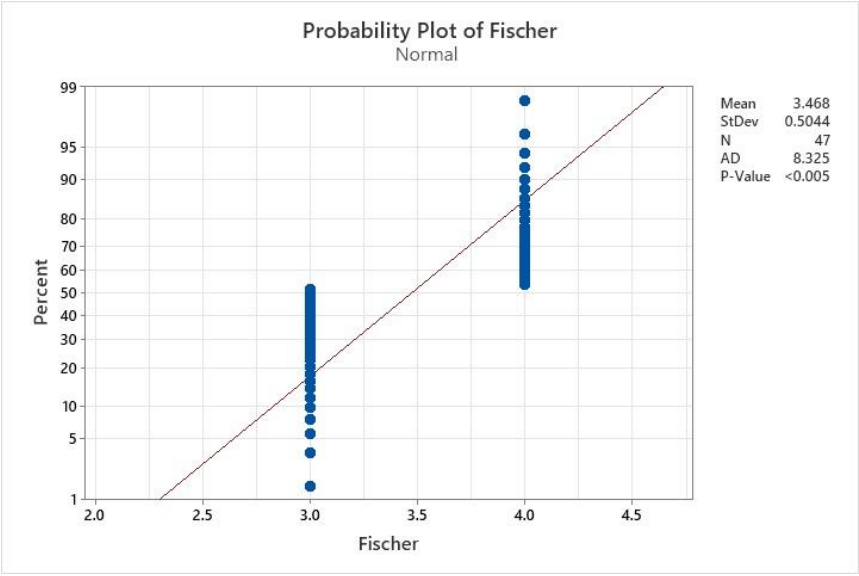

Fig. 1. The normality test for the Fischer score.

The group that underwent external ventricular drainage in the first 5 days after the onset of symptoms required an average of 7 days of hospitalization, fewer than the rest of the patients - on average 13.8 (min = 10, max = 19) *vs.* on average 21.8 (min = 12, max = 31) - and showed a better GOS discharge score on average with 0.82 (4.68 *vs.* 3.86) and 0.11 better at the time of return for follow-up (average 4.71 *vs.* 4.6). Obtaining a better GOS discharge score depending on the time of application of external ventricular drainage (EVD) was a statistically validated result using the *ANOVA* test to compare the means between 2 groups ($\alpha = 0.05$, $p<0.001$, F value > 1 – as it is shown in fig. 2 and tab. IV).

The GOS score at follow-up was 4.71 on average (min = 3, max = 5) in subjects who had DVE inserted in the first 5 days, and 4.6 (min = 3, max = 5) in the other group (fig. 3).

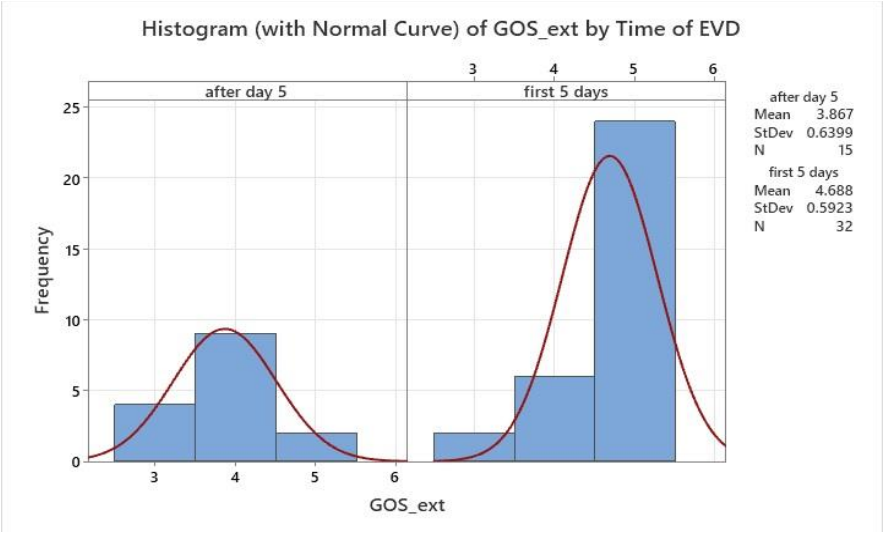

Fig. 2. GOS score at discharge depending on EVD insertion time. On the horizontal axis – GOS score at discharge. On the vertical axis - the frequency of this score in the group of subjects, depending on the time of EVD insertion.

TABLE IV

Statistical data on the number of hospitalization days according to the time of EVD insertion

Statistics

Variable	Time of EVD	N	Mean	SE Mean	StDev	Variance	Minimum	Q1	Median
DaysOfHosp	after day 5	15	21.80	1.21	4.68	21.89	12.00	20.00	21.00
	first 5 days	32	13.875	0.430	2.433	5.919	10.000	12.000	14.000

Variable	Time of EVD	Maximum
DaysOfHosp	after day 5	31.00
	first 5 days	19.000

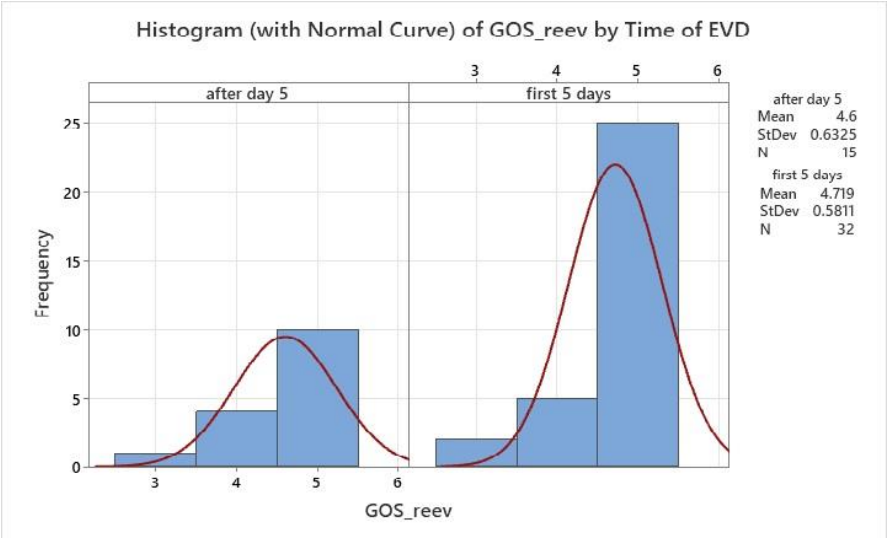

Fig. 3. GOS score at follow-up

However, regarding the differences related to GOS at discharge compared to the GOS calculated at 3-6 months, it was not possible to validate the statistical significance of the result due to the smaller number of subjects who returned for follow-up in the same service.

Following images show serial cerebral computed tomography (CT) examinations from patients in our lot of subjects.

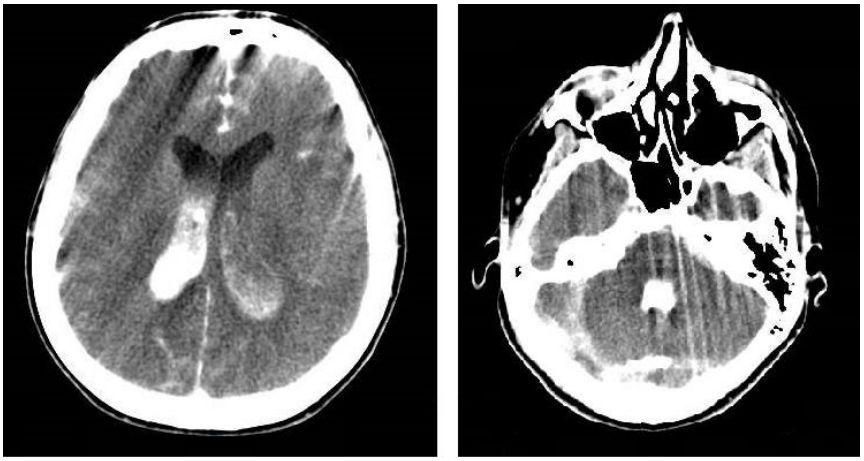

Fig. 4. Axial enhancement cerebral CT sequences from a patient with a ruptured right vertebral artery aneurysm in V4 segment, Fischer score 4: Left: thick layer of blood in the interhemispheric cisterns and in both lateral ventricles; Right: blood in the dilated fourth ventricle and surrounding the cerebellar tent. (*Collection of Neurosurgery I Clinic, Emergency University Hospital of Bucharest)*

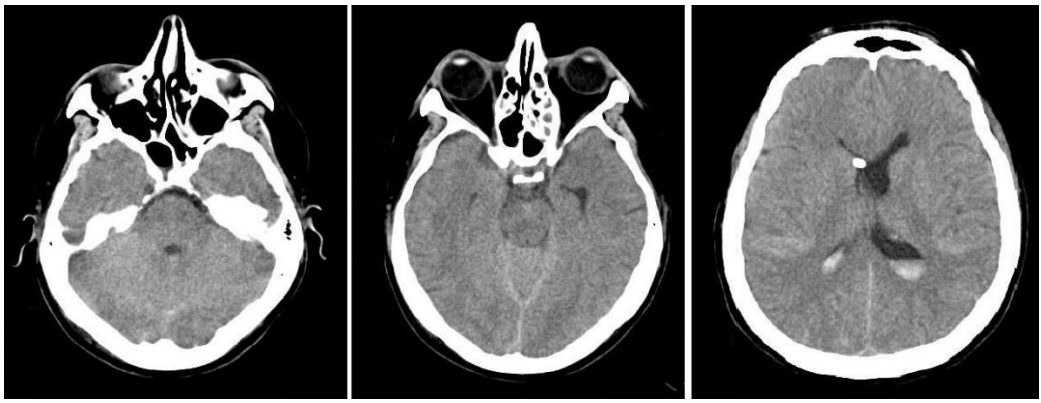

Fig. 5. Axial enhancement cerebral CT sequences from the same patient as in figure 4. Day 4 after EVD applied, almost complete remission of subarachnoid and ventricular blood and slight cerebral edema.
(*Collection of Neurosurgery I Clinic, Emergency University Hospital of Bucharest)*

DISCUSSION

Chemical washout of the subarachnoid space, by irrigating the basal cisterns with urokinase and ascorbic acid, for fibrinolytic and antioxidant effects respectively, is a method for which there is, although in small numbers, most validated date as of today's literature.

Irrigation of basal cisterns with urokinase is intended for lysis and washout of subarachnoid blood, while ascorbic acid is administered to promote the degradation of oxyhemoglobin, a highly spasmodic substance for brain vessels, in other products without spasmogenic effect. Irrigation is done from a technical point of view by installing inflow-outflow systems in the sylvian valleys (unilateral or bilateral inflow tubes) and in the opto-chiasmatic or prepontine cisterns (outflow tubes). Kodama *et al.* applied the method of chemical washing of the subarachnoid space with urokinase and ascorbic acid and obtained good results on a group of 217 patients, considering the decrease of the risk of symptomatic vasospasm in patients with Fischer III score from 37% to 2.8%. Their clinical study led to complications such as seizures, meningitis and intraparenchymal hematomas in only 4% of cases (3).

The most controversial method is given by the irrigation of the basal cisterns with Ringer's solution or urokinase and the energetic movement of the head after securing the aneurysm, this being, in fact, a mechanical method of washing the subarachnoid space.

Nguyen *et al.* (2021) obtained satisfactory results in lumbar CSF drainage in aneurysmal subarachnoid hemorrhage. In patients included in their prospective clinical study, this method reduced the incidence of clinical vasospasm, shortening hospitalization and improving the GOS score at one year (13). The mechanism of action by which this method reduced symptomatic vasospasm is probably due to the maintenance of cerebrospinal fluid circulation, thus washing the subarachnoid space of leaked blood and its products (5, 10). These findings reinforce the hypothesis of removing blood clots in the basal CSF cisterns and broaden the scope of choices for clinical practitioners to improve the

quality of treatment. However, this clinical study was performed in a relatively small group of 43 patients and the infectious risk was not negligible (10, 13).

The main disadvantages related to these methods are given by the selection of candidates, by the validation of the study results, as well as by the accessibility and acceptance of these resources by the specialists in the field.

A prospective clinical study in the United States is currently investigating whether there are significant differences in the outcome of patients with *continuous* external ventricular drainage compared to patients with *discontinuous* external ventricular drainage. The data currently available did not show arguments in favor of any of the external, continuous or discontinuous ventricular drainage methods (14).

The results of our present study suggest that early, though not immediate, intervention on the subarachnoid space in patients with high risk of developing vasospasm, in addition to complications, reduces hospitalization and in this manner also reduces the risk of nosocomial complications, offering in addition a faster social reintegration and thus reducing the costs related to neurorehabilitation. Based on these considerations, we advocate an early intervention on the subarachnoid space, by methods with washout effect, in a controlled manner, in subarachnoid hemorrhage due to vascular cause.

The risk of developing symptomatic vasospasm was estimated by placing it in a Fischer group based on the computed tomography presentation. The reduction in the risk of developing symptomatic cerebral vasospasm in these patients can be attributed to the effect of mechanical washout of the subarachnoid space by CSF drainage and by decreasing intracranial pressure.

The same result also highlights and validates the importance of mechanical intervention on subarachnoid spaces in the first 5 days after presentation.

CONCLUSIONS

Considering that a *curative treatment* of aneurysmal subarachnoid hemorrhage is out of question, this being in fact *a series of pathological phenomena* that occur causing devastating complications on brain structures, we advocate for early surgical methods that oppose the pathophysiological chain of this condition.

Adequate definition of the selection criteria of patients who can benefit from different methods of wash-out of the subarachnoid space is a key point of this type of treatment. Other key aspects are given by the moment of applying these methods in the management of SAH, ensuring the neurological safety they come with and training the specialists involved in the management of this pathology.

It is expected that ethical issues regarding the study and development of new surgical techniques on severely ill subjects will delay scientific progress in this direction.

An issue that has re-entered the surgical interest in recent years, attractive in terms of expected results, daring by reorienting from pathogenic to etiological control of cerebral vasospasm, it is expected that methods of washout the subarachnoid space in SAH of all types will become a topic of peculiar neurosurgical interest in the following decades.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

THE ASSOCIATION BETWEEN FACTOR V LEIDEN, MTHFR C667T/A1298C POLYMORPHISMS AND PREGNANCY OUTCOMES (Abstract): The present study aims to characterize the association between factor V Leiden, MTHFR C667T/A1298C polymorphisms and adverse pregnancy outcomes such as early recurrent pregnancy loss, thrombotic complications, fetal growth restriction, pre-eclamsia. **Material and methods:** We aimed to retrospectively assess the pregnancy outcomes of patients with factor V Leiden, MTHFR C667T/A1298C polymorphisms and their combination, between September 2019 and October 2020. Was determined the activity of protein C, antithrombin III and protein S activity. After isolation of blood DNA was evaluated Factor V Leiden, and MTHFR C667T/A1298C polymorphisms. **Results:** We segregated the 179 patients into 7 groups as follows: factor V Leiden mutation heterozygote and homozygote groups, patients with both factor V Leiden and MTHFR mutations, MTHFR A1298C polymorphism homozygote and heterozygote groups, and MTHFR C667T polymorphism homozygote and heterozygote groups. Although higher IVF rates were identified in the MTHFR C667T heterozygote group (23.9%) and in the FVL-homozygote group (33.3%), no statistically significant difference was calculated. Recurrent pregnancy losses were more frequently encountered in the FVL homozygote and FVL-MTHFR groups (66.6% and 66.7%), and we found a significant association between this parameter and patients with factor V Leiden and a combination of factor V Leiden - MTHFR polymorphisms ($p<0.05$). **Conclusions:** Our results suggest a strong association between factor V Leiden polymorphism, or between the combination of factor V Leiden and MTHFR polymorphism with adverse pregnancy outcomes such as thrombotic complications, early recurrent pregnancy loss and intrauterine growth restriction. **Keywords**: PREGNANCY, FACTOR V LEIDEN, MTHFR POLYMORPHISM.

Pregnancy is characterized by a hypercoagulable state, determined by increased of some coagulation factors- VII, VIII, X and von Willebrand factor activity (1), as well as a reduced fibrinolytic activity (2). These changes in the hemostatic system favor some maternal and fetal complications, which can manifest as early as con-

ception and extend during all pregnancy and also in first trimester after birth. (3). For women with acquired or inherited thrombophilia, the risks of developing pre-eclampsia (PE), placental abruption, fetal growth restriction (FGR), early and late recurrent pregnancy loss (RPL), intrauterine death and stillbirth are higher (4). However, at present the screening is routinely recommended only in presence of venous thromboembolism.

Further, the value of hereditary thrombophilia screening in complicated pregnancies is uncertain because of limitations in knowledges about its implication in development of complications and lack of evidence for effective intervention (5).

In last decades, were produced some demographic changes and thus for many women the first pregnancy is arrived after the age of 35 years and in some cases this event is obtained by an artificial reproductive technology. These women present frequently different medical complications, and the use of thrombophilia screening is needed despite the above-described limitations, especially in those that had previous pregnancy complications .

This retrospective study aims to characterize the association between factor V Leiden (FVL), MTHFR C667T/A1298C polymorphisms and adverse pregnancy outcomes such as early recurrent pregnancy loss, thrombotic complications, FGR, PE, and stillbirth.

MATERIAL AND METHODS

We aimed to retrospectively assess the pregnancy outcomes of patients with factor V Leiden, MTHFR C667T/A1298C polymorphisms, and their combination. The patients were admitted to a tertiary maternity hospital, 'Cuza Voda', Iasi, Romania, between September 2019 and October 2020. The study was reviewed and approved by the Institutional Ethics Committee of University of Medicine and Pharmacy "Grigore T. Popa" from Iasi (approval no. 17806/03.09.2019). Informed consent was obtained from all participants.

The inclusion criteria were a) pregnant patients with vascular disorders; b) positive family history for myocardial infarction, stroke or other thromboembolic complications; c) personal history of spontaneous abortions in the first trimester; d) personal history of preterm birth. We have excluded patients who used antithrombotic medication or were incapable of giving a written consent.

Blood samples were collected from 181 female patients. Blood samples were collected to the EDTA tube (five milliliters) and stored at -20°C until DNA isolation. We have determined the activity of protein C and antithrombin III using a chromogenic assay, while the protein S activity was determined using the activated partial thromboplastin time (aPTT).

Isolation of blood DNA was performed with the Qiagen kit (DNeasy Blood) according to the protocol. The concentration and quality DNA samples were evaluated by spectrophotometric method (NanoDropND1000). After analyzing the DNA samples, 179 cases were selected for evaluation. Factor V Leiden, and MTHFR C667T/A1298C polymorphisms were amplified and detected by TaqMan probes using a real-time PCR kit (Appled Biosystem). The genotyping of the obtained amplicons was performed by melting curve analysis.

Out of 181 pregnant patients, 179 were included in the study because two patients had protein C and S deficiency without any association with thrombophilic mutations. Relevant information on maternal and fetal

parameters (age, type of conception, thrombotic complications during pregnancy, PE, FGR, stillbirth, gestational age at birth, newborn weight and Apgar score) were collected in structured proforma, entered in *Microsoft Office Excel* format. Statistical analysis was performed using *SPSS software version 24.0* (IBM Corp.). Descriptive statistics and one-way *ANOVA* analysis were used for characterization of the association between thrombophilic polymorphisms and various pregnancy outcomes among study groups.

RESULTS

We segregated the 179 patients into 7 groups as follows: factor V Leiden mutation heterozygote (n=19 cases) and homozygote (n=3 cases) groups, patients with both factor V Leiden and MTHFR mutations (n= 18 cases), MTHFR A1298C polymorphism homozygote (n=13) and heterozygote (n=60) groups, and MTHFR C667T polymorphism homozygote (n=17) and heterozygote groups (n=67). The descriptive statistics for these groups and specific parameters are described in first table.

No statistically significant difference was observed between groups regarding the mother's age. Although higher IVF rates were identified in the MTHFR C667T heterozygote group (23.9%) and in the FVL-homozygote group (33.3%), no statistically significant difference was calculated.

Recurrent pregnancy losses were more frequently encountered in the FVL homozygote and FVL-MTHFR groups (66.6% and 66.7%), and we found a significant association between this parameter and patients with factor V Leiden and a combination of factor V Leiden - MTHFR polymorphisms ($p<0.05$) (Table II). The same aspect of distribution was observed in case of thrombotic complications between the FVL homozygote and FVL-MTHFR groups (66.6% and 77.8%), with a p value of less than 0.05.

The highest rates of fetal growth restriction were observed among the FVL-MTHFR group (83.4%), followed by FVL homozygote group (33.3%), with a statistically significant association ($p<0.05$) (tab. II).

Although high rates of preeclampsia were noted in the MTHFR C667T homozygote (17.6%), FVL+MTHFR (11.1%), and FVL heterozygote group (15.8%), no statistically significant association could be established (tab. II). The stillbirth rates were insignificant among all groups.

DISCUSSION

The purpose of our study was to evaluate the pregnancy outcomes among various groups with thrombophilic polymorphisms.

We have outlined the significant association between homozygotic mutations of factor V Leiden, or the mutant combination of factor V Leiden and MTHFR, with recurrent pregnancy loss, thrombotic complications and fetal growth restriction. Our results support other similar literature findings. The link between factor V Leiden mutation and recurrent pregnancy loss is controversial, as some showed a significant association, but other studies failed to prove this aspect (5-7). Sergi *et al*, conducted a meta-analysis on Western countries, and demonstrated a statistically significantly increased carrier frequency of FVL mutation homozygous in women with early recurrent pregnancy loss (8). Moreover, Cobzaru *et al*, demonstrated that the concomitant presence of MTHFR A1298C and Factor XIII V34L gene polymorphism had a significant association for recurrent pregnancy loss (9).

The disagreement between FVL studies may be due to the difference or heterogeneity in the patients' population so that single nucleotide polymorphisms need to be considered, along with the specific geographic

area (10-13). Our study included Caucasian women from Eastern Europe, and the results suggested a stronger bond between early recurrent pregnancy loss and the combination of mutant factor V Leiden-MTHFR carriers.

The association between factor V Leiden and thrombotic complications in pregnancy and beyond is well established in the literature (14, 15), the mutant variant increasing the risk of venous thromboembolic events with more than 20–30% (16). Our results support the literature findings and outline a strong association between factor V Leiden homozygotic mutation or heterozygotic mutation and its combination with MTHFR, and thrombotic complications in pregnancy, respectively.

As for fetal growth restriction, a recent systematic review by Howley *et al*, suggested an increased risk of giving birth to an intrauterine growth restricted fetus for women with factor V Leiden polymorphisms (17). Although we have identified a significant association between FGR and homozygotic mutation of FVL or FVL-MTHFR, we could not obtain the same results in case of preeclampsia, even though some studies suggest an important involvement of these mutation in its pathogenesis (18-20).

The major limitation of our study is the small number of cases. Further large cohort studies will allow a better statistical analysis. Moreover, multiple single nucleotide polymorphisms should be studied in order to better characterize the association between patients with thrombophilia from different regions and adverse pregnancy outcomes.

CONCLUSIONS

Our results suggest a strong association between factor V Leiden polymorphism, or between the combination of factor V Leiden and MTHFR polymorphism with adverse pregnancy outcomes such as thrombotic complications, early recurrent pregnancy loss and intrauterine growth restriction.

We failed to outline a link between these genetic polymorphisms and preeclampsia, even though the scientific literature suggests a significant association.

Further studies should focus on larger cohorts of patients, along with specific single gene polymorphisms in order to complete the picture of adverse pregnancy outcomes in the context of thrombophilia.

CONFLICT OF INTEREST AND FUNDING

Authors declare that there is no conflict of interest, and they received no funding for this study.

AVAILABILITY OF DATA AND MATERIALS

The data used to support the findings of this study are available from the corresponding author upon reasonable request.

AUTHORS' CONTRIBUTIONS

All authors had equal contributions. All authors gave the final approval of the version submitted for publication. All authors read and approved the final manuscript and agreed to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

ETHICS APPROVAL AND CONSENT TO PARTICIPATE

The study was reviewed and approved by the Institutional Ethics Committee from the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi (approval no. 17806/03.09.2019). Informed consent was

obtained from all participants and/or their legal guardians included in the study. All research was performed in accordance with relevant guidelines/regulations.

CLINICAL EXPERIENCE IN PARTIAL THICKNESS BURNS TREATMENT USING LMW-HYALURONIC ACID TOPICS (Abstract): **Aim:** To describe the importance of hyaluronic acid topics in partial thickness burns treatment, corresponding to each chronological stage of the burn injury, reducing the healing time, with a good control of pain management during the dressing change and improving the quality of newly formed tissue. **Material and methods:** Descriptive study developed on 20 patients treated between December 2019 - January 2021, including I, IIA, IIB burn lesions and skin graft donor zones, on a total surface area of 5-10% each, located on different zones of the body such as upper/lower limb and trunk. **Results**: For all the patients (aged 21-58 years old, 14 females), we preceded the low molecular weight hyaluronic acid (LMW-HA) application by the lesion debridement with topics based on hyaluronic acid and collagenase. In 7 cases we performed surgical excision of IIB lesion followed by reconstruction using split skin grafts, harvested from the thigh. To stimulate the detersion of the burned tissues, we combined the proteolytic effect of the collagenase with the action of the negative wound pressure therapy system (NPWT) in 7 cases. We obtained good functional and aesthetic results in all the cases, with total healing time of 14-35 days. **Conclusions:** Because of the contribution as a modulator to many of the biological processes, LMW-HA (200 kDa) became a part of therapeutic options for burns lesions and skin graft donor zones. The ease of use, biocompatibility, better esthetic and functional results were also considered as important points. **Keywords**: LOW MOLECULAR WEIGHT, HYALURONIC ACID TOPICS, BURNS, DONOR ZONES, SKIN GRAFT.

The Hyaluronic Acid (HA) is a nonsulfated glycosaminoglycan, met as a component of the connective tissues, but also of the epithelial and neural tissues. Being an important element, part of the extracellular matrix, HA is implicated in the healing process, as a modulator of the angiogenesis, inflammation and skin regeneration (1).

The hyaluronic acid can be obtained from human or animal sources (for example, human umbilical cords or bovine vitreous humors, the skin of sharks), but with the "price" of protein residuals with immunogenic effects (2). Therefore, the bacterial technology is considered as an important way to obtain high-purity HA (3). HA has different biological effects depending on its molecular weight (4). A molecular weight

of 20–200 kDa allows HA to influence important biological processes such as embryonic development and wound healing (5). High molecular weight HA (HMW-HA) has an anti-angiogenic effect; low molecular weight HA (LMW-HA) is pro-angiogenic and pro-inflammatory (6). For these properties LMW-HA is preferred for wounds medication. The topics based on LMW-HA can influence the local evolution of wounds, by reducing the healing time and controlling the qualities of the newly formed tissue (7).

MATERIAL AND METHODS

Given the good clinical evidence of efficacy and safety of HA in the management of acute and chronic wounds, we have started to treat some patients presenting first- and second-degree burns with topics based on LMW-HA, with the aim of reducing the healing time and improving the newly formed tissue.

We evaluated a group of twenty patients, treated in the Burns Unit of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, between December 2019 and January 2021.

We included in our study patients with I, IIA, IIB burn lesions and skin grafts donor zones, on a total surface area of 5-10% each, located on different anatomical regions, such as upper/lower limb and trunk.

From the whole group of patients (aged 21-58 years old, fourteen female) only 5 were smokers (one of them declaring 40 cigarettes per day). Considering the comorbidities, most of the cases (17 patients) declared at least one illness as diabetes (5 patients- 25%), leg venous insufficiency (7 patients- 35%), and urinary infection (5 patients- 25%). In ten cases (50%) we identified two preexistent comorbidities for each patient, with important effect on the healing process (as diabetes, immunodeficiency, hepatitis, ulcerative colitis, severe anemia).

Respecting the moment of the first clinical evaluation, five patients came within the first 24 hours after the injury (25%), 11 patients came at 24-72 hours distance from the accident (55%) and 4 patients came to the hospital at 5-7 days distance from the accident (20%). We consider the moment of the first evaluation of main importance, knowing that the evolution of a burn injury depends on the general and local therapy applied within the first 24-48 hours after the accident (8).

In 13 cases (65%) we identified I and II A degree burns and 7 patients (35%) had II A and II B degree injuries.

Eight patients (40%) suffered injuries covering 5-7% from the total body surface area (tbsa) and in twelve cases (60%) the burns covered 8-10% tbsa. In 12 cases the burns were situated on the lower limbs, in 4 cases on the upper and lower limbs and in 7 cases on the limbs and trunk regions.

Four patients (20%) had burns situated on the perineum region and on the buttocks, already contaminated with *Escherichia coli* at the moment of the first clinical evaluation.

All the skin grafts donor zones had negative secretions from the bacteriological point of view (7 cases). The wound's secretions were sterile (from the first clinical examination) in 8 cases (40%) and contaminated with *Staphylococcus epidermidis* in 4 cases (20%). Eight patients arrived to the first consultation with infected wounds (gram-negative bacteria).

Data were systematized and centralized in an SPSS 24.0 database and processed using the appropriate statistical functions.

A 95% confidence interval was used in data presentation.

TREATMENT PROTOCOL

In all the cases, the treatment with HA topics was preceded by the lesion debridement and cleaning with chlorhexidine and sterile saline solution.

For IIA burns, the detersion process was stimulated using local applications of the ointment containing HA and collagenase, for the first 3-5 days of evolution/once per day.

If the bacteriological examination confirmed wound bacterial contamination, we used for local applications the ointment containing HA and silver once per day, for the next 5-7 days (up to the hospital discharge), in the case of second-degree superficial burns.

For second-degree deep (II B) burns, with surgical indication, we performed early wound excision and local reconstruction using split skin grafts (7 patients, 3 patients with leg's circumferential and constrictive burns). The surgery was performed under loco-regional anesthesia in all the cases (rachianesthesia - for lower limb, perineum region and buttocks or combination between infraclavicular block and rachianesthesia, for upper limb burns and skin grafts harvested from the thigh). For two patients, with second deep burns on the trunk, we needed general anesthesia.

We used negative pressure wound therapy (NPWT) to stimulate the burn cleansing and the healing process in 5 cases-25%, (also in addition to the skin graft for 3 cases).

The burned necrosis was excised using the electric dermatome (with a thickness of 0.3 mm). The skin grafts were harvested from one thigh, using the electric dermatome, with a thickness of 0.2 mm, on a surface of maximum 3% tbsa.

To prevent the bleeding, we covered the skin grafts donor zones with Calcium-alginate dressing for the first 48 -72 hours after surgery; then, to stimulate the donor zones healing and prevent the local infection, we used daily applications with HA and silver topic for the next 5-7 days (up to the hospital discharge day). We recommended the use of LMW-HA topic for local applications, twice a day, for the first-degree burns (preceded by local cleaning with saline solution), starting with day one after injury. For second-degree superficial burns and skin grafts donor zones, we used the topic twice a day (preceded by local cleaning with liquid soap and saline solution), after the patient's discharge day.

We evaluated the progression of the healing process (we estimated the initial wound surface and thickness - using a laser Doppler blood perfusion imagery for the burned surface and the dermatome gradations, for the skin grafts donor zones). We measured the wound dimensions in the first day (the day of first clinical examination), in the eighth day of evolution (after the injury/ after surgery) or of clinical follow up (some patients arrived at the first clinical examination a few days after the injury), in the fifteenth, twenty first, twenty eighth, respectively thirty fifth day after the first clinical examination (for the cases with larger wounds). We calculated the healing rate for each period of time, and we estimated the wound healing rate per day, as a medium value.

We evaluated the blood levels of proteins and hemoglobin at the patient's admission, before and after surgery sessions, before the discharge day. We monitored the blood pressure levels, pulse rate, diuresis,

temperature and the wound's bacterial colonization for all the patients.

To estimate the local pain during the bandage removal and daily wound cleaning, we used a pain scale with ten levels, VAS - visual analogue scale (9). For pain assessment, we used paracetamol and ketoprofen.

RESULTS AND DISCUSSION

We selected for evaluation the skin grafts donor zones because they are surgical wounds with very good chances of healing. As skin graft harvesting is a surgical procedure, it takes place in sterile conditions and the wound's dimensions (surface, thickness) are mathematically established (we can precisely control the dimensions using the electric dermatome). The bleeding is controlled, and the epithelialization sources are preserved, because a split skin graft is, usually, harvested with 0.2-0.3 mm thickness (within the superficial dermis) (10, 11).

We considered that it would be interesting to compare the healing process of a "standardized wound" (the skin graft donor zone) and an accidental injury (burn) on different/symmetric anatomic regions, at the same patient. For this reason and considering that the dedicated skin grafts donor zones are the thighs, we selected for evaluation burns localized mainly on the lower limbs (16 patients, 80%).

We evaluated the daily healing progress on both, skin grafts' donor zones and burns, in area and in volume.

An essential role in quantifying the healing process is the ability to determine the size of a wound. Without determining the area and volume of a wound, we cannot assess its healing rate, appreciate the topic's efficiency, nor can we optimally use negative pressure therapy or local topics, as this is in relation to these sizes (12).

The results for the daily healing progress of the same wound, in area and in volume, were identical in the case of skin grafts donor zones evaluation, and comparable for the burned injuries (differences of 0.01 between the daily progress rate, estimated on surface and in volume) .

The dimensions of the skin grafts donor zones were between 24,000 square mm and 60,000 square mm (1.2% tbsa-3% tbsa, with a median of 2.1% tbsa) and the volumes between 4,800 and 12,000 cubic mm.

The duration of the healing process varied between 14-23 days, with an average value of 19.28 days. The healing process depended on the total burned surface, patient's age and comorbidities, the delayed period of first clinical evaluation (4 hours-7 days).

The daily rate of healing process, for skin grafts donor zones, varied between 4.34% and 5.88% from the initial wound surface or volume as well (with a medium value of 4.92%).

For the same 7 cases that needed surgery (excision and skin grafting) we followed the healing daily progression for the burned wounds. We found, for similar wound's surfaces, a lower rate of epithelialization per day.

The dimensions of the burned injuries, non-grafted zones, varied between 7,200 square mm (0.36% tbsa) and 47,200 square mm (2.36% tbsa), with a medium value of 19,667 square mm (0.98% tbsa) and the volumes between 3600 cubic mm and 10 160 cubic mm, with a median of 4,953 cubic mm.

The duration of the healing process for the burned injuries (non-grafted zones) varied between 21-35 days, with an average value of 26.5 days. The daily rate of heal-

ing progression for these injuries varied between 2.36% and 4.41% from the initial burned surface (non-grafted zones), with a medium value of 3.12% (fig. 1).

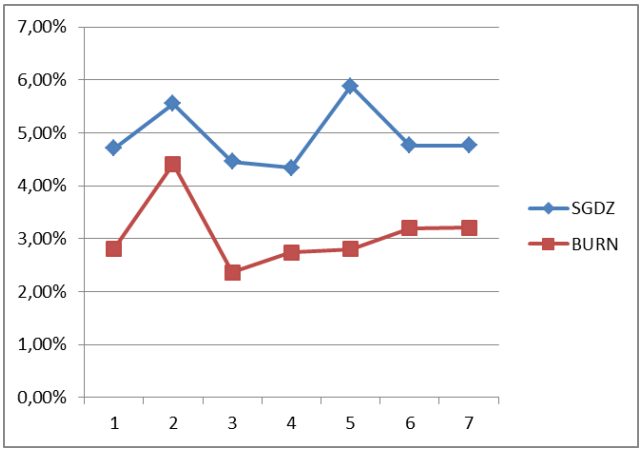

Fig. 1. SGDZ-skin graft donor zones (the daily healing rate for the 7 patients with surgical excision and skin grafts). BURN - the wounds that did not receive the excision and skin grafts (the daily healing rate for the same 7 patients, but on the burned surfaces which were not grafted)

Considering the results, we can conclude that the skin grafts donor zones will usually heal faster than the IIA burned skin, even if we use different and very efficient devices to help a burn to cure (as NWPT or HA topics). It is the difference between the etiology and pathophysiology of the two types of wounds, the surgical and the accidental one, that decides the evolution process to complete healing. We monitored the SGDZ bacteriological, as well. The results were negative secretions in all the 7 cases.

A skin graft donor zone is a surgical wound with the best chances to heal. In the absence of bacterial contamination, on a patient with good nutrition (normal proteins and hemoglobin) the skin grafts donor zones start to heal immediately after the surgery, with no delay (13-16).

A burn injury is, in fact, a skin necrosis, with different thickness levels on different areas (depending on the etiology, anatomic region, gender, age, microorganisms' density). The healing process can start only after the wound detersion, after the necrotic tissues are eliminated naturally (under enzymatic action or bacterial action). This process takes time, and the risk of wound deepening is always real.

The use of HA topics can stimulate the wound's detersion process (the ointment containing HA and collagenase) and shorten the total healing time. In 3 cases with 5-7 days delay in presenting to the hospital, we combined the efficiency of the HA and collagenase topic with the NPWT action, and so we managed to avoid surgery.

In the cases with contaminated or infected wounds, we added the ointment containing HA and silver in local wound therapy, for its efficient action against bacteria with very good results.

We used LMW-HA topics on the skin grafts too, beginning with day 7-9 after

surgery, in all the 7 cases, with very good esthetic and functional results (better local hydration, lower level of pain during the bandage changing and mobilization, faster local integration of skin grafts, more elastic scars, reduced itching, better pigmentation of newly formed skin).

Comparing these results with our experience using other topics in application on SGDZ, we concluded that the LMW-HA ointment is easier to apply on the wound. The local application determines less pain, assure better level of wound hydration (the patients feeling that the skin becomes "constrictive", the patient's need to repeat the topic application many times a day), calms the itching, enables better level of patients early mobilization. The esthetic effect is obvious, as the elasticity and pigmentation of the postoperatively scars are of good quality and the patients are satisfied by the result. For 13 patients (65%) with I, IIA and IIB burns we did not perform excision and reconstruction using skin grafts. The protocol followed in these cases combined the detersive action of NPWT or/and the HA ointment containing collagenase, with the efficient topics active against microorganisms (based on HA and silver) and the epithelial stimulation effect induced by LMW-HA topics.

Not all the patients arrived for the first clinical evaluation immediately after the accident (only 5 patients, 25%), not all the patients had negative secretions from the bacteriological point of view, at their arrival to the hospital (only 8 patients, 40%).

In twelve cases, (4 patients arrived at the first clinical evaluation immediately after the injury, 20%) the wounds were contaminated/colonized with one or two microorganisms, some of them with multiple resistance to antibiotic therapy.

Five patients (25%) had both, negative and respectively positive wounds' secretions, on different anatomic regions, on different wounds. In these cases, we compared the daily healing rate on both negative, respectively positive wounds, in area and in volume and we found significant differences (for example, case number 8: from 4.54% daily on the negative wounds to 2.85% daily on the positive wounds, for similar burn degree) (fig. 2).

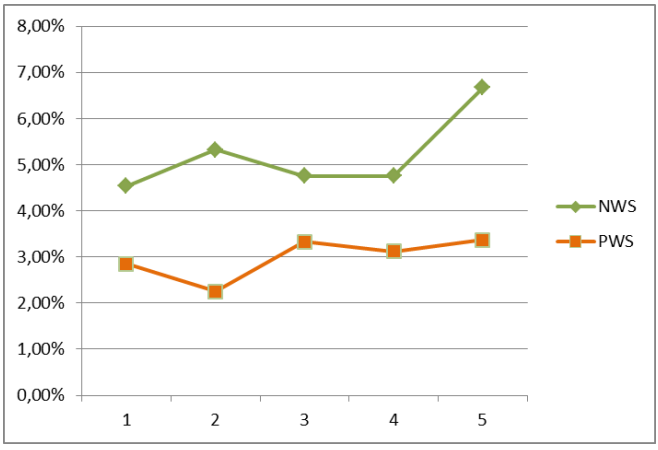

Fig. 2. NWS-negative wound' secretions. PWS-positive wound' secretions – (the daily healing rate for the 5 patients treated with HA topics, who had concomitant wounds with bacteriological negative, respectively positive secretions).

For the patients with both, negative and, respectively, positive wounds' secretions on different regions, the wounds' dimensions varied between 19,200 and 36,800 square mm (with a median of 24,420 square mm) for negative wounds, respectively from 34,800 to 50,600 square mm (with a median of 35,500 square mm) for the positive wounds. The tissue volumes varied between 3,840 and 9,120 cubic mm (with a median of 5,052 cubic mm) for negative wounds, respectively from 4,960 to 11,880 cubic mm (with a median of 7,794 cubic mm) for positive wounds.

We evaluated the daily healing progress on both types of burns, at the same patient, in area and in volume.

The results varied between 2.85% to 3.37% from the initial burned area in positive wounds, comparative with 3.57% to 6.67% from the initial burned area, for the negative wounds, for the same patient.

The duration of the healing process varied between 15 - 28 days, with an average value of 21.8 days, for negative wounds, respectively from 21 - 43 days, with an average value of 31.2 days, for positive wounds. We can conclude that the healing process is usually delayed by the wound infection, on the same patient, for lesions comparable from the dimensions and location point of view (figs. 3, 4, 5).

Bacterial colonization of the wound represents an important element for the progression of the healing process.

For example, a quantitative analysis of the distance of aggregation for bacteria from the wound surface showed that those composed of *P. aeruginosa* were located significantly deeper in the wound bed than those composed of *S. aureus* (10). This distribution of aggregates could explain the fact that *S. aureus* on the surface of the skin forms a biofilm that specifically inhibits wound healing mechanisms, thus avoiding the effects of local immunity and allowing other microorganisms to colonize and infect the lesion.

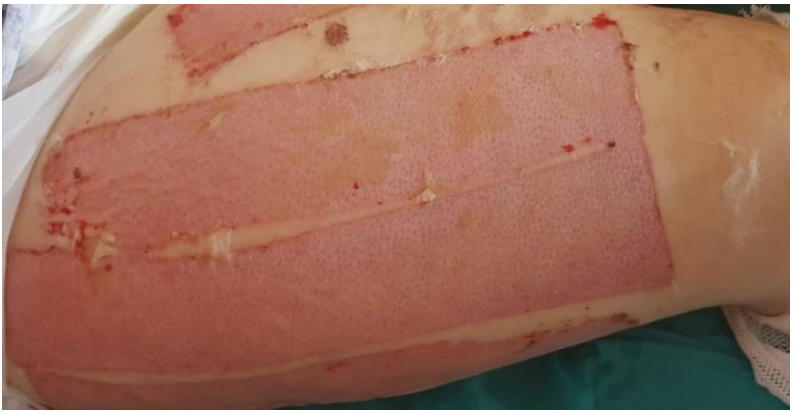

Fig. 3. Female, 47 years old, fire burn, IIA+IIB degree burn, both legs circumferential, 10% tbsa - skin grafts donor zones - day 8 after surgery, negative secretion, first day for local application of LMW-HA topic, twice a day; immediately after harvesting the graft we used alginated gauze for wound protection (Calcium alginate dressing with silver, days 1-4 and wide-meshed cotton webbing, impregnated with a non-active ingredient containing, skin-neutral ointment, days 5-8)

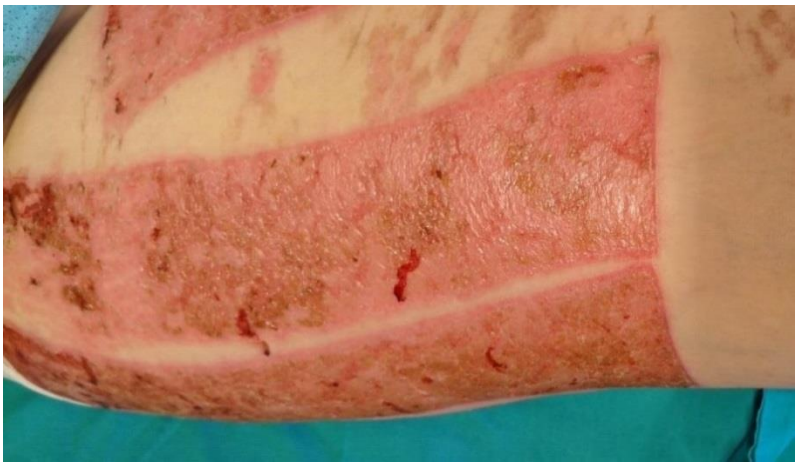

Fig. 4. Female, 47 years old, fire burn, IIA+IIB degree burn, both legs circumferential, 10% tbsa - skin grafts donor zones - day 14 after surgery, 7 days of local LMW-HA topic application, twice a day.

Fig. 5. Female, 47 years old, fire burn, IIA+IIB degree burn, both legs circumferential, 10% tbsa - skin grafts donor zones - day 21 after surgery, 14 days of local LMW-HA topic application, twice a day.

We found a correlation between the patient's late presentation to the first clinical examination (16 cases-80%) and the local bacterial colonization (12 cases with positive results of bacteriological examination-60%). There is another interesting correlation between some specific comorbidities (as diabetes, urinary infection, ulcerative colitis-50 % of cases) and the presence of Gram-negative bacteria (8 patients-40% of cases).

We used the HA ointment combined with silver in daily applications on the burned areas colonized by bacteria and we obtained a good result (good wound hydration, the persistence of a silver film on the wound surface, visible for a period of 10-12 hours after the application, smaller

quantity of secretion, lower level of local pain associated to the patient's mobilization).

CONCLUSIONS

The objectives of wound healing are to minimize blood loss, replace defects with new tissue (granulation tissue followed by scar tissue) and restore the intact epithelial barrier as soon as possible.

In these cases, healing requires tissue oxygen supply, proteins and other nutritional factors, a humid local environment, a favorable inflammatory process condition, wound debridement and correction of biological conditions. In some cases, this is easily achieved, and in others considerable effort is required.

We combined the surgical procedures with non-surgical protocols following the main goal: to promote a better and faster wound healing. The surgical protocol consisted in tangential excision of the necrotic tissue and reconstruction with skin grafts, or surgical debridement of the wound associated with local application of HA ointment containing collagenase. The non-surgical protocol used NPWT systems, in local applications stages for 5-7 days/stage and/or HA topics. The use of NPWT combined with collagenase stimulated the necrotic tissue elimination.

The use of HA topics was adapted to wounds' requirements. The local applications of HA ointment containing collagenase on recent burns stimulated the natural removal of the necrotic tissue. We used the HA ointment containing silver for the wounds with bacteria colonization, to manage the local infection and promote the faster healing.

The LMW-HA topic had a favorable outcome in all the cases, to stimulate the epithelialization and for a better scar management. The local applications of LMW-HA topics on the skin grafts donor zones, burns and skin grafts promoted a fast wound healing and reduced the pain level.

Healing is an interdependent and intricate process involving complex interactions between cells, the cellular microenvironment, biochemical mediators, and the extracellular matrix, molecules that normally lead to a restoration of affected tissue function.

The use of HA topics for the local treatment of superficial and intermediate burns was very efficient, and we observed a stimulating effect on the healing daily progress for both –skin grafts and donor zones, too. Due to the pro-angiogenic and pro-inflammatory effects, the LMW-HA topics manage to hurry the healing progression and favors the scars to become more elastic, less pigmented, with lower risk of tearing after the contact with clothes, better integrated and easier to be accepted by the patient. HA topics with LMW are painless, when applied on the wounds, promote a better wound or scar hydration, so the patient's mobility is higher.

Last, but not the least, the use of HA topics is related to the hospitalization period shortening and lower hospitalization costs, assuring a better scar quality and higher level of satisfaction for the patient.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest to disclose, and they received no specific funding regarding this scientific research.

ELECTROHYDRAULIC *VERSUS* ELECTROMAGNETIC EXTRACORPOREAL SHOCK WAVE LITHOTRIPTER. WHAT LESSONS HAD WE LEARNED? (Abstract): **Aim:** The present study aimed to determine if there is a difference in efficacy and safety in the use of electrohydraulic versus electromagnetic lithotripters when used for the treatment of a single kidney stone of 10-20 mm. **Material and methods:** We performed a retrospective study on a group of 106 patients with a single kidney stone which was treated by lithotripsy with devices that had different sources of shock wave generation. **Results:** The overall success of the treatment using electrohydraulic lithotripsy was 85.2% for kidney stones of 10-14 mm and 66.7% for kidney stones of 15-20 mm while for electromagnetic lithotripsy, the success rate for stones of 10-14 mm was 97% and 88.7% for kidney stones of 15-20 mm. Regarding postprocedural complications, we found 7 cases of steinstrasse, all in patients with kidney stones of 10-15 mm, of which 2 in the group of patients treated with electromagnetic lithotripsy and 5 in the case of those treated by electrohydraulic lithotripsy. We also found two post-procedural cases of perirenal hematomas, one in each group. None of the patients required additional therapeutical measures. **Conclusions:** There were no significant differences in the efficiency rate and safety profile for the treatment of kidney stones of 10-20 mm. However, the electromagnetic lithotripter has definite advantages in terms of the quality of the tracking and focusing system of the calculus compared to the bifocal system of the electrohydraulic lithotripter. **Keywords:** KIDNEY STONE, ELECTROHYDRAULIC LITHOTRIPSY, ELECTROMAGNETIC LITHOTRIPSY, EFFICIENCY OF FRAGMENTATION, SAFETY PROFILE.

Urolithiasis is a major public health problem worldwide. Although there are still no statistics for Romania, studies available show that incidence rates range from 7-13% in North America while in Europe about 4.7% of the population develop a lithiasis episode during their lifetime. For example, in Germany studies show that every year approximately 750,000 patients are diagnosed with kidney stones (1, 2).

Over the last 30 years, the treatment of urolithiasis has undergone dramatic changes, especially since Chaussy *et al.* introduced the use of extracorporeal lithotripsy (SWL) in clinical practice (3).

Currently, European Urology Association (EAU) guidelines suggest that for kidney stones smaller than 20 mm, treatment options should include, primarily, extracorporeal lithotripsy or percutaneous nephrolithotomy (PCNL), while for stones that exceed this size, gold-standard treatment is PCNL (4).

The increase of the safety profile of extracorporeal lithotripsy has been achieved through the emergence of new generations of lithotripsy, which use different shock wave generation mechanisms. Of course, the price paid to technology for the increase of the patient's comfort was a weaker disintegration of the stones and a higher rate of re-intervention (5). Extracorporeal lithotripsy using the first generations of lithotripters such as Dornier HM-3 had excellent efficacy but many disadvantages, one of the most important being the need to use general anesthesia.

Since its introduction in the medical practice, various generations of lithotripters have been developed, the difference between them consisting in the mechanism of generating shock waves. Thus, we considered it appropriate to perform a retrospective, comparative analysis between two lithotripters of a different generation, using different technologies, respectively, electrohydraulic and electromagnetic.

MATERIAL AND METHODS

To achieve this goal, we enrolled patients treated in the Extracorporeal Lithotripsy Department of Iași, "Dr. C. I. Parhon" Clinical Hospital, from January 2018-January 2019 and from February 2020-February 2022, respectively, these two intervals correspond to the use of two lithotripters with different technology. The size of the calculi was from 10-20 mm, introduced by performing paired cases. The exclusion criteria were the presence of multiple kidney stones or simultaneous ureteral stones.

Analgesia was achieved by topical application of a gel containing piroxicam, lidocaine, and cyclobenzaprine, and in very rare cases, by intramuscular administration of Tramadol. All procedures were performed in one-day hospitalization by a single urologist with significant experience in the field of extracorporeal lithotripsy and the average time between two procedures was approximately 30 ± 2 days.

The post-procedural examination was performed after 4 weeks and involved radiological examination by renal ultrasound and kidney-ureter-bladder radiography. Patients in whom radiological examination did not show certainly the presence or absence of the remaining fragments were excluded from this study. The case was considered refractory to extracorporeal lithotripsy if, after performing two procedures, no satisfactory fragmentation was found to allow the elimination of the fragments and subsequently required an endourological gesture.

SWL success was defined by the patient's stone-free status or the presence of CIRF (clinically insignificant residual fragments) below 4 mm.

RESULTS

The study includes a number of 106 patients with single kidney stones. In group A were introduced 54 patients with kidney stones treated with the second-generation electrohydraulic lithotripter, KS-88-4. Group B included patients who received extracorporeal lithotripsy using

the Dornier Sigma Compact electromagnetic source lithotripter. The characteristics of the two groups of patients are shown in first table.

TABLE I

Comparative results

	Group A	Group B	p
Total number of patients	54	52	
• Men	28	22	0.429
• Women	26	30	
Location of the calculus			
• Lower calyx calculus	9	6	
• Middle calyx calculus	3	3	0.75
• Upper calyx calculus	-	-	
• Renal pelvis calculus	42	43	
Laterality			
• Right	28	31	0.37
• Left	26	21	
Size of the calculus			
• 10-14 mm	34	34	0.95
• 15-20 mm	20	18	
Steinstrasse			
• 10-14 mm	-	-	0.437
• 15-20 mm	5	2	
Perirenal hematoma			
• 10-14 mm	-	-	0.99
• 15-20 mm	1	1	

Regarding the results obtained with the electrohydraulic lithotripter KS-88, the overall success rate was 85.2% - for kidney stones with dimensions between 10-14 mm the success rate was 88.23% (fig. 1), while for kidney stones between 15-20 mm, the calculated efficiency was 66.7% (fig. 2).

Using the Dornier Sigma Compact electromagnetic lithotripter, the overall success rate efficiency for stones of 10-14 mm was 97%, while for the ones in the category 15-20 mm the efficiency was 88.7%. Regarding the patients in the examined groups, we did not find statistically significant differences either for the 10-14 mm category (p=0,693) nor for the 15-20 mm category (p=0.202) in terms of the efficiency of the two lithotripters.

Regarding the complications (fig. 3), we report 7 cases of steinstrasse, all of which are found in patients with calculi with dimensions between 15-20 mm - 5 cases from electrohydraulic lithotripsy and 2 cases from electromagnetic lithotripsy. All steinstrasse cases were also treated by extracorporeal lithotripsy, the target being the large distal fragment. We also found two cases of perirenal hematomas, detected by post-procedural ultrasound, one case in each group. Fortunately, neither of the two

patients required complementary procedures and a 3-month reevaluation revealed complete resorption of the hematoma. In our study, there were no significant differences in the incidence of post-procedural complications, neither for steinstrasse (p=0.29) nor for perirenal hematomas (p=0.97).

The 10 patients who had calculi between 10-14 mm refractory to extracorporeal lithotripsy subsequently benefited from ureteral stenting followed by retrograde intrarenal surgery (RIRS).

From the group of the patients with stones between 15-20 mm (14 cases), in whom SWL did not give the expected results, 9 received a percutaneous procedure while 5 patients underwent RIRS.

DISCUSSION

Since the introduction of lithotripsy in daily practice, various types of lithotripters have been developed, the main difference between them being the mechanism of producing shock waves. Broadly speaking, all lithotripters - regardless of the generation they belong - are composed of the power source, the wave focusing system, the coupling system, the treatment table and the control panel. The first focus (F1) is the place of wave generation, and the second focus (F2) is the place where energy converges, and fragmentation takes place. The electrohydraulic lithotripter we used, KS-88-4, made in China, uses energies between 18 and 20 kV and has a focal area of 4 cm^2 and the system of the stone's localization is bifocal, consisting of two fluoroscopy tubes located on either side of the generator in an oblique position.

In the case of electrohydraulic lithotripters, shock waves are produced by two electrodes and an ellipsoidal reflector. High voltage energy (15.000-20.000 V) is discharged by two electrodes, resulting in water vaporization and the creation of bubbles that subsequently collide and generate a high energy pressure wave that propagates spherically through the liquid, then the energy is focused and concentrated with a specially designed system. The energy at the level of the fragmentation focus (F2) in the case of electrohydraulic lithotripters is dependent on the voltage used and has variations of about 45%, which translates into a loss of energy ranging from 15-50%.

Electromagnetic lithotripters apply an electric current to an electromagnetic coil located inside a water cylinder. The discharged energy will cause a shock wave to propagate planar along with the cylinder. Electromagnetic lithotripsy does not require the replacement of electrodes, thus having the advantage that they can generate several hundred thousand pulses without requiring special maintenance and, on the other hand, the energy variation is only 3% and the fragmentation focus is a flat surface rather than a point as in the case of electro-

hydraulic lithotripters (6). The Dornier Sigma Compact lithotripter, used in our department, is equipped with a C-arm type fluoroscopic tracking system, of isocentric type, allowing rotation around a single focal point, which translates into a precise alignment between radiological detection and focusing of shock waves. For this type of lithotripter, the focal point has a size of 8.1x 105 mm and the applied pressure is 51 mPa (7).

Numerous authors have compared the results and safety profile of various types of a lithotripter, but the results are extremely varied. This variability of the data in literature seems to be generated by the lack of standardization in the evaluation of the results as well as of the numerous working protocols. These results differ not only between different lithotripsy centers whose results are published but even between two urologists using the same device within the same center (8). Precisely for this reason, the efficiency results, obtained with lithotripters of older generations, fall within a wide reference range, between 47-92%. In a similar study, conducted by Anila *et al.*, using lithotripters of different generations in patients with lithiasis characteristics similar to the patients in our study, they obtained an overall stone-free rate per month of approximately 95% for baseline calculi with dimensions between 10-20 mm (9). These results are slightly different from the results obtained by us, with the second-generation lithotripter - for calculi of 10-14 mm we obtained success rates of 81.5% and 70% for stones of 15-20 mm. In the specified study, there is no clear distinction between the two size categories of stones, the authors specifying the overall success rate of lithotripsy for stones of 10-20 mm. With the electromagnetic lithotripter, the results obtained by the mentioned authors are also slightly different, the success being 78%, compared to the results obtained by us, respectively 92.6%. The explanation for this phenomenon may arise from the fact that in the cited article, there is a significant percentage of lower calyx stones (60% in the cited article, compared to 12% of patients with lower calyx stones in our group). This is certainly very relevant and underlies the difference in the results mentioned, Weld *et al.*, pointing out in their research that pelvic lithiasis and stones at the pyeloureteral junction have a better fragmentation and elimination than calyx stones, especially lower calyx ones (10).

In a study comparable to ours, involving patients with similar lithiasis characteristics, Kavano *et al.*, obtained fragmentation rates of stones of 86%, a percentage similar to that obtained by us but stone-free rates of 54% in the first month and 68% after 3 months(11). These results are similar to those obtained by us, stating that, overall, in our study, the stone-free rate at one month, in the group of patients treated with Dornier Sigma S lithotripter, was 52% but we also considered the presence of the clinically insignificant lithiasis fragments (CIRF), which in our group of patients constituted an important percentage, respectively 32.7%. In the previous study, the percentage of patients who presented with CIFR was not specified.

As in our statistics, a slight superiority of the efficiency of electromagnetic lithotripsy versus electrohydraulic lithotripsy, Sheir and collaborators obtained rates of 72% and 68%, respectively, for kidney stones, stating that the statistical difference

was insignificant. Elbaset *et al*., using electromagnetic lithotripsy, obtained for kidney stones a fragmentation and clearance rate of lithiasis fragments of 58.6%, much lower than the results we report (12). This difference is explained by the fact that in the specified study, all kidney stones were evaluated before the procedure by computed tomography, with densities of over 1000 UH, so hard stones. In our center, there was no possibility to perform pre-procedural computed tomography.

Our results using the electromagnetic lithotripter are also confirmed by other studies conducted on large groups of patients. Thus, Tan *et al.*, on a batch of 1666 kidney stones, performed 2326 extracorporeal lithotripsy sessions - an average of 1.4 sessions for each stone, achieving an overall success rate of 81%. Of these patients, 495 required recurrences of extracorporeal lithotripsy, resulting in a retreatment rate of 29.7%. Regarding the stone-free rates obtained by Tan and his collaborators for kidney stones (53%), these are similar to the values obtained by us, respectively 52% (13).

A study with results superior to the one carried out by us is the one published by Korhmann and collaborators. They report a stone-free rate efficiency of 91% for kidney stones, the explanation for this very large difference being primarily reevaluation - respectively 5 months after the performance of lithotripsy - and the use of energies at very high levels involved the use of general anesthesia compared to our study. We used analgesia performed by applying a local anesthetic gel. Moreover, the success reported by Korhmann also comes from the fact that lithotripsy was performed in a proportion of 25% in patients who previously underwent endourological intervention (retrograde ureteroscopy, PCNL) (13, 14), while in our study, for stones in the 10-20 mm category, extracorporeal lithotripsy was the first-line treatment. In fact, in our center, almost all kidney stones larger than 20 mm are referred to as an interventional method, extracorporeal lithotripsy for this category of stones being performed exceptionally (anesthetic risk , anatomic conditions).

A well-known complication of extracorporeal lithotripsy is steinstrasse consisting in the accumulation of obstructive lithiasis fragments following the procedure. This complication is sometimes asymptomatic and transient but can cause severe problems. The data published in the literature are in the range of 2-10%, this being directly proportional to the size of the calculus (15, 16). The data obtained by us, 1.85% (EH) and 3.84% (EM), respectively, are within this range. However, for the size of the calculi analyzed by us, Soyupek and collaborators report different data, respectively 15.7% but data closer to those reported by us, were published by Javanmard *et al*., respectively 6.6% incidence of steinstrasse for kidney stones (17, 18).

The limitations of our study are primarily the relatively small number of identified paired cases, but also the impossibility of pre-procedural tomographic evaluation of patients to determine the hardness of the stones by measuring their densities and lack of analysis of the composition of fragments through infrared spectroscopy after SWL .

CONCLUSIONS

Even though the two lithotripters we considered use completely different tech-

nologies, there were no significant differences in the efficiency rate and safety profile for the treatment of kidney stones of 10-20 mm. However, the electromagnetic lithotripter has definite advantages: can provide shock waves that are equal in intensity and has a better quality of the tracking and focusing system of the calculus with a lower X-Ray exposure compared to the bifocal system of the electrohydraulic lithotripter.

Moreover, the spark gap lithotripter has the disadvantage of the need to periodically replace the electrodes compared to electromagnetic technology which is time consuming and cannot offer the same level of energy throughout the procedure.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

SERUM FERRITIN AS A DIAGNOSTIC BIOMARKER FOR KAWASAKI DISEASE

Kawasaki disease is an acute febrile systemic vasculitis of unknown etiology. Kawasaki disease diagnosis depends on the use of adjuvant diagnostic markers, such as echocardiographic findings and laboratory biomarkers, including C-reactive protein, erythrocyte sedimentation rate, albumin, alanine aminotransferase, aspartate aminotransferase, white blood cell count, hemoglobin, platelet count, and pyuria. Although the laboratory findings observed in Kawasaki disease are not specific enough to conclusively establish a diagnosis, they can be useful, particularly in patients with a high suspicion for Kawasaki disease. Diagnosis of Kawasaki disease is occasionally delayed because it is solely based on clinical symptoms. Previous studies have attempted to identify diagnostic biomarkers for Kawasaki disease. Recently, patients with Kawasaki disease were reported to have elevated serum ferritin levels. This study aims to investigate the usefulness of the serum ferritin level as a diagnostic biomarker for distinguishing Kawasaki disease from other acute febrile illnesses. Blood samples were obtained from pediatric patients with Kawasaki disease and those with other acute febrile illnesses between December 2007 and June 2011 for measuring various laboratory parameters, including serum ferritin levels. In patients with Kawasaki disease, laboratory tests were performed at diagnosis and repeated at 2, 14, and 56 days after intravenous immunoglobulin treatment. At the time of diagnosis, serum ferritin levels in patients with Kawasaki disease (188.8 μg/L) were significantly higher than those in patients with other acute febrile illnesses (106.8 μg/L, P=0.003). The serum ferritin cut-off value of 120.8 μg/L effectively distinguished patients with Kawasaki disease from those with other acute febrile illnesses, with a sensitivity and specificity of 74.5% and 83.3%, respectively. Serum ferritin may be a useful biomarker to distinguish Kawasaki disease from other acute febrile illnesses. (Kim SH, Song ES, Yoon S, Eom GH, Kang G, Cho YK. Serum Ferritin as a Diagnostic Biomarker for Kawasaki Disease. *Ann Med Lab* 2021; 41(3): 318-322).

SENESCENT FIBROBLASTS BETA-GALACTOSIDASE INDUCED BY EXTRACELLULAR VESICLES OBTAINED FROM MSC-iPSC UNDER THE ACTION OF VARIOUS MODULATORS (Abstract): The absolute majority of published experimental data involve mesenchymal stem cells, although the possibilities offered by the use of pluripotent stem cells reprogrammed from mesenchymal stem cells are practically infinite. **Aim**: The goal of our study was represented by tracking the effects of stimulation and inhibition of multiple functional, intracellular pathways of senescent dermal fibroblasts in culture, in the presence of microvesicles released from pluripotent stem cells reprogrammed from mesenchymal stem cells. **Material and methods**: We used flow cytometry to measure the production of the beta-galactosidase level by dermal fibroblasts in culture after 30 passages and ultraviolet treatment. **Results**: Reduction of β-galactosidase concentrations in senescent dermal fibroblasts was evident upon administration of exosomes (approximately 20% on average) and exosomes co-administered with: LY-294002 (a highly selective PI3K kinase inhibitor, 41% on average); nutlin-3 (which stabilizes the non-genomic actions of p53, respectively the MDM2/p53 pathway, 63% on average); rapamycin (which stimulates autophagy and the mTOR pathway and related ones, 62% on average); and metformin (a pharmacologically active substance, considered a reprogrammer of energy metabolism, 73% on average). **Conclusions**: Exosomes derived from pluripotent stem cells induced from mesenchymal stem cells, administered in the culture medium of senescent dermal fibroblasts, can modify the degree and evolution of the senescence of these last cells by potentiating, activating, or stimulating some intracellular pathways of biological signal transduction, but especially through epigenetic reprogramming of energy metabolism. **Keywords:** MSC-iPSC, ENERGY METABOLISM REPROGRAMMING, EXOSOMES, FIBROBLASTS, MSC, EPIGENETICS.

The skin is the largest human organ and has a multitude of functions. It is well known that the healing of a skin wound/injury activates an impressive number of unique functionalities, which include cascaded cellular mechanisms and which, at the same time, represent a unique process in nature. While regeneration defines the specific replacement of tissue, with reference to the superficial epidermis, mucosa, or fetal skin, skin repair processes actually represent a non-specific form of healing, in which the

injury is healed by extensive fibrosis and scar formation. The clear physiological objective of wound repair in mammals ultimately equates to the formation of scars, a phenomenon that is directly proportional to the extent of the inflammatory process throughout healing (1).

The healing of injuries is thus a complex and dynamic process, at the same time supported by a multitude of cellular processes, which require strict coordination to be able to efficiently repair the damaged tissue. Alteration of cellular behaviors, which occurs for example in diabetes and the aging process, can lead to significant impairment of healing and the appearance of chronic, non-healing lesions. This chronic evolution represents a particularly important socio-economic burden due to its high prevalence and recurrence. Thus, there is a great need for a better understanding of all the complex mechanisms underlying healing (2).

Chronic lesions become superinfected with bacteria, which aggravates the inflammatory process. Keratinocytes in chronic lesions exhibit aberrant activation, resulting in hyperproliferation and impaired local migration. A very large number of cells present at the level of chronic lesions (for example, macrophages and fibroblasts) become evolutionarily senescent and transform into a senescence-associated secretory phenotype (or called SASP), which further perpetuates senescence, activates the massive release of reactive oxygen species (ROS) and further intensifies the inflammatory process. Moreover, the large amounts of final products of advanced glycation that appear contribute, at the same time, to the development of the inflammatory process and cellular senescence at the level of the lesion. Together, all these characteristics produce excessive tissue destruction and alter cellular functions, preventing normal healing (3).

Mesenchymal stem/stromal cells (MSCs), due to their competences to establish skin cells such as fibroblasts and keratinocytes, as well as their special attribute to suppress inflammation in the inflammatory focus of wounds have attracted increasing attention among researchers. Thus, exosomes transfer practical cargoes (e.g., growth factors, cytokines, miRNAs, etc.) from mesenchymal stem cells to target cells, thus affecting extraordinarily important biological functions of recipient skin cells, such as migration, the expansion and also the secretion of particularly important elements of the extracellular matrix (for example, collagen of various types) (4).

The goal of our study was represented by the tracking of the effects of stimulation and inhibition of multiple intracellular functional pathways of senescent dermal fibroblasts in culture, in the presence of microvesicles released from pluripotent stem cells reprogrammed from mesenchymal stem cells.

MATERIAL AND METHODS

The laboratory research that we carried out aimed at quantifying the evolution of the degree of senescence of dermal fibroblasts (senescent cells) by evaluating β-galactosidase through flow cytometry (5, 6), in a bi-culture, in the presence of pluripotent stem cells reprogrammed from mesenchymal stem cells (in culture) or under the action of exosomes/microvesicles released from MSC-iPSCs, in the form of concentrated supernatant, administered in the culture medium.

Storage rat dermal fibroblasts (cell line no. 1) were grown under standard laborato-

ry conditions and tested for β-galactosidase through flow cytometry after passage 1, passage 10, passage 20, and passage 30. To obtain senescent dermal fibroblasts, they were irradiated with ultraviolet, λ=315 nm, 80 mJ/cm^2, and then multiplied by means of 30 consecutive passages.

To obtain MSC-iPSCs, we used the episomal method with iPSC reprogramming vectors and the specific Stemline culture medium (Invitrogen), in full agreement with the manufacturer's specifications. We preferred this technique because the use and manipulation of potentially genetic material included in the "dangerous" chapter are totally excluded. The growth and multiplication of pluripotent stem cells reprogrammed from mesenchymal stem cells were done using an Alvetex 3D bio support -a gift from Reinnervate-, since a series of other experiments demonstrated the maximum efficiency for this type of support.

For the large-scale evaluation of possible interactions between the cell lines we used, first of all, a series of preconditioning factors for MSC-iPSCs: 1% O_2, 1 μM angiotensin II, vitamin E 0.5 μM, and low doses of lipopolysaccharide (0.1 μM) (7).

For exosome separation, the culture medium of pluripotent stem cells induced from rat aortic smooth muscle cells was centrifuged up to 100,000xg (8).

The active substances we used for the various experiments and protocols including senescent dermal fibroblasts were: 1 μM LY294002, 1 μM nutlin-3, 1 μM rapamycin, and 2 μM metformin.

All the experimental results obtained during the present research were processed entirely by statistical methodologies, using a number of well-known and optimized tests over time and for medical research, among which the One-Way ANOVA test should be mentioned, which was also completed, only occasionally, with the Student-Newman-Keuls test.

RESULTS

During the development and multiplication processes, strictly monitored, MSC-iPSCs presented a series of characteristics of embryonic morphology, constantly observed in cell culture conditions, being otherwise undifferentiated, even organizing themselves in the form of aggregates/organoids, demonstrating it therefore clearly belongs to this cell type.

To verify the viability of experimentally reprogrammed pluripotent stem cells from mesenchymal stem cells, grown on 3D Alvetex bio support, preconditioned with 1% O_2, angiotensin II, vitamin E, and low doses of lipopolysaccharide, we used 0.1 μM 5-carboxyfluorescein (succinimidyl ester), with excitation/emission maxima 498/517 nm (green fluorescence) and flow cytometry as stated. The best qualitative and quantitative development in the case of pluripotent stem cells experimentally reprogrammed from mesenchymal stem cells, starting from the 2nd passage in culture, we obtained when we multiplied them in a preconditioning medium that contained a concentration of only 1% O_2. We considered this increase to always be 100% (n=5 experiments for each set, data not shown, personal observation). Comparatively, development in the presence of angiotensin II in the preconditioning medium was 79.23±2.74% (n=5), in the presence of vitamin E it was 72.39±2.87% (n=5) and in the presence of lipopolysaccharide was 76.72±1.79% (n=5).

In addition, the most important β-galactosidase reduction effects in senescent dermal fibroblasts in monoculture, in the presence of exosomes/microvesicles at a

concentration of 0.01%, obtained in concentrated form by ultracentrifugation of the MSC-iPSC supernatant, were observed when we developed these latter cell types in a medium preconditioned with 1% O_2. Thus, under these conditions, we found amplification of β-galactosidase reduction in senescent dermal fibroblasts by approximately 20% (on average).

In a series of experiments, a number of senescent dermal fibroblasts were treated with 1 μM LY294002, considered to be a highly selective PI3K kinase inhibitor, as well as 0.01% exosomes obtained from the supernatant of MSC-iPSC. We found amplification of β-galactosidase reduction in senescent dermal fibroblasts by approximately 41% (on average) when MSC-iPSC were multiplied in a medium preconditioned with 1% O_2 (fig. 1).

In the second series of experiments, a different batch of senescent dermal fibroblasts was treated with 1 μM nutlin-3, which stabilizes with great efficiency the non-genomic actions of p53 (MDM2/p53 pathway), as well as 0.01% exosomes obtained from the supernatant of MSC-iPSC. We found amplification of β-galactosidase reduction in senescent dermal fibroblasts by approximately 63% (on average) when MSC-iPSC were multiplied in a medium preconditioned with 1% O_2 (fig. 2).

In the third series of experiments, an important number of senescent dermal fibroblasts were treated with 1 μM rapamycin, which stimulates autophagy and the mTOR pathway and related ones, as well as 0.01% exosomes obtained from the supernatant of MSC-iPSC. We found amplification of β-galactosidase reduction in senescent dermal fibroblasts by approximately 62% (on average) when MSC-iPSC were multiplied in a medium preconditioned with 1% O_2 (fig. 3).

Finally, in the fourth series of experiments, a totally different batch of senescent dermal fibroblasts was treated with 2 μM metformin, a pharmacologically active substance, considered a reprogrammer of energy metabolism, as well as 0.01% exosomes obtained from the supernatant of MSC-iPSC. We found amplification of β-galactosidase reduction in senescent dermal fibroblasts by approximately 73% (on average) when MSC-iPSC were multiplied in a medium preconditioned with 1% O_2 (fig. 4).

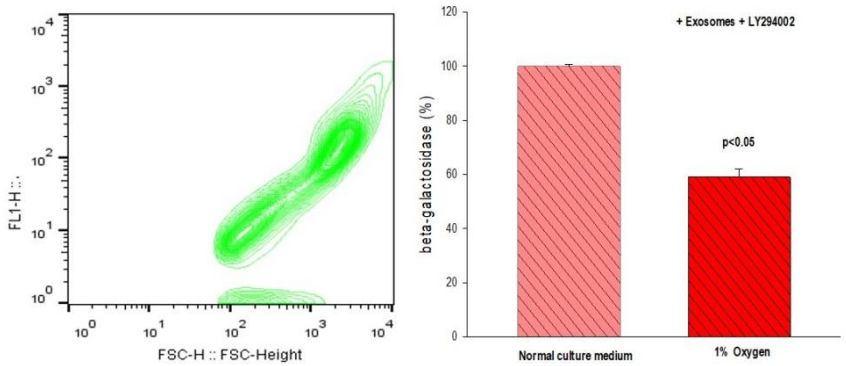

Fig. 1. Quantification by flow cytometry of β-galactosidase in senescent dermal fibroblasts in monoculture, when multiplied in the presence of LY294002 (1 μM) and MSC-iPSC-released exosomes, preconditioned in 1% O_2 medium. $p<0.05$ as compared to the normal culture medium

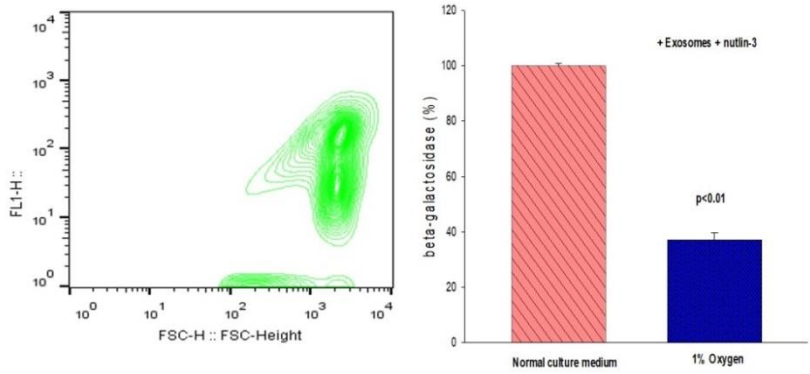

Fig. 2. Measurement of β-galactosidase in senescent dermal fibroblasts, when developed in the presence of nutlin-3 (1 μM) and MSC-iPSC-released vesicles, preconditioned in 1% O_2 medium. $p<0.01$ as compared to the normal culture medium.

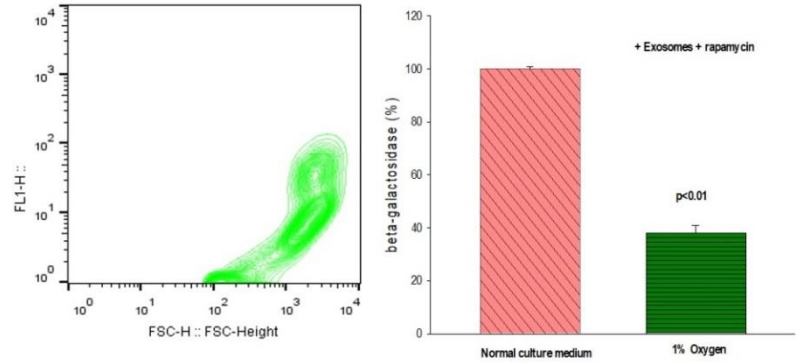

Fig. 3. Determination of β-galactosidase in senescent dermal fibroblasts, when cultured in the presence of rapamycin (1 μM) and MSC-iPSC-released extracellular vesicles, preconditioned in 1% O_2 medium. $p<0.01$ as compared to the normal culture medium.

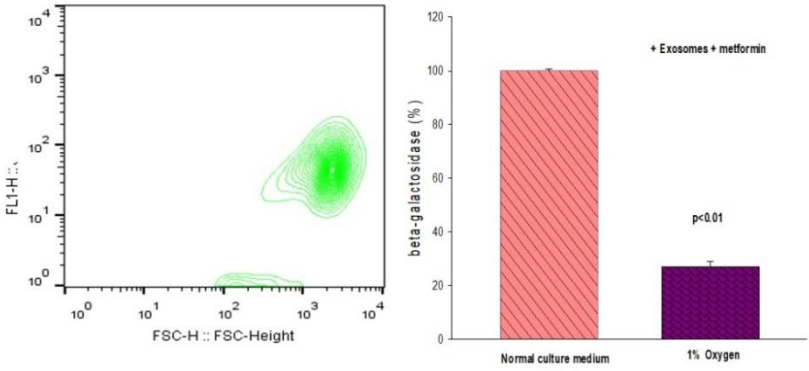

Fig. 4. Evaluation of β-galactosidase in senescent dermal fibroblasts in monoculture, when grown in the presence of metformin (2 μM) and MSC-iPSC-released extracellular microvesicles, preconditioned in 1% O_2 medium. $p<0.01$ as compared to the normal culture medium.

DISCUSSION

Mesenchymal stem cells (MSCs) have the potential to be used in cell-based regenerative therapies. Currently, hundreds of clinical trials are using MSCs for the treatment of various diseases. However, MSCs are low in number in adult tissues; they show heterogeneity depending on the cell source and show limited proliferative capacity and early senescence in vitro cultures. These elements negatively affect the regenerative capacity of MSCs and therefore limit their use for clinical applications. As a result, unique methods to generate induced MSCs (iMSCs) from induced pluripotent stem cells have actually been verified. Advancement and optimization of procedures for generating iMSCs from induced pluripotent stem cells is necessary to assess their regenerative capacity in vivo and in vitro. In addition, it is essential to compare iMSCs with primary MSCs (separated from adult tissues) regarding their safety and efficacy. Careful examination of the promising properties of iMSCs in vitro and their long-term interaction habits in animals is essential for their transfer from bench to patient (9, 10).

Human derived pluripotent stem cells (hiPSCs) are indispensable resources for the production of premium, separated cells in unrestricted quantities for both basic research studies and scientific use. They are particularly useful for studying human disease systems in vitro, making it possible to avoid the ethical problems of human embryonic stem cell research. However, there are substantial constraints when using traditional flat culture approaches, which specifically impair cell growth, differentiation performance, maintenance of stability, and facilitation of multicellular 3D structure. Embryoid bodies, which are multicellular aggregates spontaneously created from iPSCs in the suspension system, can help address these issues. Due to the unique microenvironment and cell communication within the structure of embryoid bodies, which a 2D culture system cannot achieve, they have actually been widely applied in hiPSC-derived differentiation and show considerable advantages especially in culture scale-up, performance improvement differentiation and ex vivo simulation. Embryoid bodies can also be used in early prediction of the differentiation capacity of iPSCs (11, 12).

Both mesenchymal stromal cells and fibroblasts can be isolated from almost all organs. Mesenchymal stromal cells represent the most favorable cellular healing agents with regenerative potential, and fibroblasts are among the most abundant cell types with the ability to preserve homeostasis. Due to the promising and attractive properties of MSCs, they have been well studied and thus their differentiation capacities, immunomodulatory potentials, as well as gene expression profiles are determined. Fibroblasts and mesenchymal stromal cells have been observed to have comparable morphology, gene expression patterns, surface markers, expansion, differentiation, and immunomodulatory capabilities. Therefore, it is difficult to differentiate these two types of cells. Epigenetic signatures, i.e., the methylation patterns of cells, are the only appealing functional distinction between them. Such substantial similarities show that these two cells may be associated with each other (13, 14, 15).

Cellular senescence is currently recognized as one of the nine characteristics of the aging phenomenon. Recent experimental data show, on the other hand, the major involvement of senescent cells in

tissue aging and even more so in some age-related diseases. Skin is considered to be an ideal model for the study of aging phenomena. If features of senescence are evident with skin aging, the senescent phenotype is different in different skin cell types. Moreover, the origin of cellular senescence in the skin is still far from being known and multiple origins are possible. These aspects reflect the mosaic nature of skin aging (16).

Skin aging is the most visible and obvious manifestation of the body's aging and can directly serve as a predictor of life expectancy and health status. However, it is the human desire for very long-lasting beauty that further exacerbates the interest in this subject, and therefore considerable means and efforts are devoted to studying the mechanisms of skin aging through both basic and applied research. Any type of interest, medical and non-medical, is generally welcome for the development of research in the field of the skin system, it being clear that all the results of these studies can be of great help in our attempt to deepen the understanding of complex molecular and biological processes, the type of cellular and developmental signaling, as well as the immunological type, manifested at the level of this vast organ. In fact, the skin is an ideal and relatively handy organ for observing and analyzing the impact of possible extrinsic and intrinsic driving factors of aging (17, 18).

At the skin level, aging is manifested by the appearance of photodamage and skin atrophy, with the consequent reduction of underlying tissues and impaired barrier function. To determine whether rapamycin, a drug already approved by the US authorities, which targets the mechanistic component of the mTOR complex, can reduce senescence and, at the same time, markers of aging in human skin, an exploratory, placebo-controlled interventional study was conducted, in a strictly controlled clinical dermatology setting. Topical rapamycin was observed to significantly reduce p16INK4A protein expression, consistent with a significant reduction in cellular senescence. This tissue change was accompanied by an important and relative improvement in the clinical appearance of the skin and even histological markers of aging, as well as an important increase in collagen type VII, which is an essential component of basement membrane integrity (19).

Increasing evidence suggests that chronic inflammation and senescence underlie the development of many severe age-related diseases, given that both biological processes appear to be directly proportional to the degree to which the body ages. However, until now, the existence of any specific gene related to inflammation or senescence that is common to different species or different tissues has remained unknown. Thus, these potential markers of aging could greatly help to identify possible targets for therapeutic interventions in conditions associated with aging phenomena and could also help us to deepen our understanding of the main mechanisms of aging. In addition, it was very interesting to note the experimental fact that genes involved in aging-related processes tend to be much more tightly controlled in long-lived people compared to middle-lived people. These observations could suggest the existence of a general genetic level, which would affect the lifespan of any individual. Taken as a whole, such a descriptive study has made a major contribution to a better understanding of the genetic signatures common to aging phenomena, as well as the patterns of

aging that may be tissue-specific in particular (20).

Senolytics are a relatively new class of drugs believed to selectively eliminate senescent cells. Thus, the first senolytic drugs, which include dasatinib, quercetin, fisetin, and navitoclax, were discovered using a hypothesis-only approach. The most aggressive senescent cells are highly resistant to apoptosis and show hyperstimulated anti-apoptotic pathways, which can protect them from their own secretory phenotype associated with senescence, a fact that allows them to survive, even if the neighboring cells are eliminated. On the other hand, senolytics transiently deactivate these pro-survival complexes / pathways, inducing apoptosis of those senescent cells, which have a tissue-destructive SASP. Since it takes weeks to restore senescent cell mass, senolytics can be administered intermittently in a hit-and-run approach. In a number of preclinical models, it has been shown that senolytics can delay, prevent, or significantly improve body fragility, tumorigenesis, but also cardiovascular, neuropsychiatric, hepatic, renal, and musculoskeletal disorders, pulmonary conditions, but also eye, hematological, metabolic, and skin conditions, as well as organ transplant complications, but also those of radiotherapy and, last but not least, those of cancer treatment. Early pilot tests for a number of senolytics strongly suggest that they do indeed decrease senescent cell mass, reduce inflammatory processes, and improve frailty in humans. Clinical trials involving their use in diabetes, idiopathic pulmonary fibrosis, Alzheimer's or COVID-19, osteoarthritis, osteoporosis, eye disease, bone marrow transplantation, and last but not least, in the case of the childhood cancer survivor, are in progress or have just begun (21, 22, 23).

Senescent cells, which are able to release factors in the microenvironment that cause inflammation and dysfunction, assimilating to the so-called secretory phenotype associated with senescence (also known as SASP), increase numerically with aging and, at the same time, at the level of multiple etiological sites chronic diseases. Senolytic-type pharmacological compounds, including the combination of dasatinib and quercetin, can selectively eliminate senescent cells through a mechanism of transient deactivation of pro-survival complexes, which protect them from their own apoptotic environment. Thus, in the first clinical trial in which senolytics were used, dasatinib and quercetin significantly improved physical functions in patients with idiopathic pulmonary fibrosis, a fatal disease inextricably associated with senescence. However, to date, no research has directly demonstrated that senolytics can reduce the number of senescent cells in humans. On the other hand, in the case of the combination with dasatinib and quercetin, the mass of senescent cells in humans would be significantly reduced (24).

CONCLUSIONS

The most important β-galactosidase reduction effects in senescent dermal fibroblasts in monoculture, in the presence of exosomes/microvesicles at a concentration of 0.01%, obtained by ultracentrifugation of the supernatant of pluripotent stem cells reprogrammed from mesenchymal stem cells, were obtained when we grew these latter types of cells in medium preconditioned with 1% O_2.

Reduction of β-galactosidase concentrations in senescent dermal fibroblasts was

evident upon administration of exosomes (approximately 20% on average) and exosomes co-administered with: LY-294002 (a highly selective PI3K kinase inhibitor, 41% on average); nutlin-3 (which stabilizes the non-genomic actions of p53, respectively the MDM2/p53 pathway, 63% on average); rapamycin (which stimulates autophagy and the mTOR pathway and related ones, 62% on average); and metformin (a pharmacologically active substance, considered a reprogrammer of energy metabolism, 73% on average).

All these results suggest that exosomes derived from pluripotent stem cells induced from mesenchymal stem cells, administered in the culture medium of senescent dermal fibroblasts, can modify the degree and evolution of the senescence of these last cells by potentiating, activating, or stimulating some intracellular pathways of biological signal transduction, but especially through epigenetic reprogramming of energy metabolism.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research

NEWS

HYPERMAGNESEMIA REDUCES THE RISK OF INTRACRANIAL ANEURYSMS: A MENDELIAN RANDOMIZATION STUDY ON 23,829 INDIVIDUALS OF EUROPEAN ANCESTRY

Serum magnesium levels have been extensively studied for subarachnoid hemorrhage after intracranial aneurysm (IA) rupture as a treatment for vasospasm however its influence regarding aneurysm formation and progression has not been researched yet. The authors have used a mendelian randomization approach for 5 single nucleotide polymorphisms as variables for serum magnesium in a genome-wide association study in 23,829 individuals of European ancestry. The results proved an association between higher serum magnesium concentration and lower risk of all IAs, as well as unruptured and ruptured IAs examined separately. Also, at least partially, the results suggest that magnesium mediates the role of blood pressure in IA. Overall, this study is the first to identify a potential causal association between serum magnesium concentrations and risk of IA and it provides preliminary evidence for further research regarding the role of magnesium in IA management (Larsson SC, Gill D. Association of Serum Magnesium Levels With Risk of Intracranial Aneurysm: A Mendelian Randomization Study. *Neurology* 2021: 10.1212/WNL.0000000000012244 / doi:10.1212/wnl.0000000000012244).

Kv POTASSIUM CHANNELS AND RELAXATION OF RAT SMALL MESENTERIC ARTERIES BY HYDROGEN PEROXIDE

Kv POTASSIUM CHANNELS AND RELAXATION OF RAT SMALL MESENTERIC ARTERIES BY HYDROGEN PEROXIDE (Abstract): H_2O_2 is an endothelium-derived hyperpolarizing factor (EDHF). The effects of exogenous H_2O_2 may vary with the vascular bed and experimental conditions. Various contributions of different K^+ channels and of cyclic GMP have been shown for the relaxing effect of H_2O_2 in small arteries from different species and vascular beds. **Aim:** Here we studied the involvement of Kv channels in H_2O_2-induced relaxation of vascular smooth muscle. **Material and methods:** We used de-endothelised rings of rat small mesenteric arteries. **Results:** H_2O_2 induced similar relaxations of rings pre-contracted by either norepinephrine (NE) or phenylephrine (PHE). Inhibition of H_2O_2 effect in the case of NE was complete with 4-aminopyridine (4-AP), a blocker of Kv channels, as shown recently by another group, using the same vascular preparation. The inhibition of H_2O_2 effect by 4-AP was weaker in the case of PHE than in the case of NE. **Conclusions:** Based on our results, and also on the recent findings from other laboratories, we may suggest that, at least in rat small mesenteric arteries, the relaxation induced by H_2O_2 is mediated to a different extent by Kv and by other mechanisms, depending on the contracting agent. Endogenous endothelium-derived H_2O_2 could activate various smooth muscle K^+ channels and thus functionally compensate for decreased NO availability. **Keywords:** HYDROGEN PEROXIDE, OXIDATIVE STRES, ENDOTHELIUM-DEPENDENT RELAXATION, RESISTANCE ARTERIES, EDHF, POTASSIUM CHANNELS.

As we have also mentioned in some of our most recent studies (1, 2, 3), we have a sustained interest in endothelial function and dysfunction (1, 2, 3, 4, 5, 6) and also in various aspects of oxidative stress (7, 8, 9, 10). Our work in such areas is placed on the background of an ongoing wide interest in: (a) endothelium-dependent relaxation (EDR) of the vascular smooth muscle (VSM), including EDH-mediated EDR, i.e., the EDR mechanisms mediated by endothelium-dependent hyperpolarization (EDH) (11, 12, 13, 14); (b) oxidative stress in relation with vascular dysfunction (15, 16). In this context, we decided to further examine now the effect of exogenous hydrogen peroxide (H_2O_2) in de-endothelised rings of rat small mesenteric arteries, based on our very early study (17); i.e., starting from our twenty years old data, which were

obtained shortly after the very first studies regarding either the mechanism of VSM relaxation by H_2O_2 (18, 19) or its role as an endothelium-derived hyperpolarizing factor (EDHF) (20, 21). Beside the general interest mentioned above, the present study has particular reasons, such as: (a) the mechanism of VSM relaxation by H_2O_2 is still incompletely explained and may vary due to many factors (13, 18, 19, 22, 23, 24), as we have also stated in our earlier paper (17); (b) the role of H_2O_2 as EDHF is now far better known and understood (better than twenty years ago or even than just five years ago), but it clearly has many sources of variability for its importance in EDH-mediated EDR and for the actual mechanisms involved (5, 6, 13, 18, 19, 20, 24).

Vascular reactivity, including EDR, is a key factor for local blood flow and for arterial blood pressure. It is very well established (11, 12, 13, 14, 24), as we have also underlined repeatedly (1, 2, 3, 5, 6), that EDR in resistance arteries is: (a) largely independent of nitric oxide (NO) synthase and cyclooxygenase; (b) mediated by EDH, which is based on endothelial Ca^{2+}- activated K^+ channels (IK1 with intermediate conductance (iK) and SK3 with small conductance (sK)). As in our previous papers (1, 2, 3, 5, 6), here the term of endothelial dysfunction denominates any endothelial malfunction that favors vasoconstriction vs. vasodilation. Again, as we cited in our recent studies (1, 2, 3), EDH-mediated EDR is important in: functionally opposing sympathetic vasoconstriction (25); flow autoregulation, myogenic response, and vasomotion (12); compensation of the endothelial dysfunction resulted from lower NO availability/effectiveness (but is also involved in pathogenesis of endothelial dysfunction and hypertension) (14, 26, 27, 28, 29, 30).

In fact, in the present study we examined the relaxing effect of exogenous H_2O_2 in de-endothelised small mesenteric arteries of the rat precisely due to the importance of endothelium-derived H_2O_2 in EDH-mediated EDR described right above, in this last paragraph of the introduction.

MATERIAL AND METHODS

Male adult Wistar rats (~200 g) were euthanized. Jejunal loops were removed and placed in physiological saline solution (PSS), containing (mM): NaCl 119; KCl 4.7; $CaCl_2$ 2.5; $MgSO_4$ 1.2; $NaHCO_3$ 25; KH_2PO_4 1.18; glucose 5.5. In PSS at ~5°C, 1 mm rings from first order branches of superior mesenteric artery (~0.15 mm diameter) were dissected (ocular x32, objective x1) and mounted on stainless steel wires in small vessel wire myographs connected to a PC through an AD converter. The endothelium was removed before mounting, by passing a rough hair through the lumen of the vascular fragment. The rings were then oxygenated (95% O_2 + 5% CO_2) and kept at 37°C (pH 7.2-7.4). After 30' equilibration under 1 g passive tension (PSS replaced every 15'), the rings were checked for the absence of EDR by 10^{-5} M acetylcholine upon contraction by 10^{-5} M phenylephrine. Relaxation induced by each H_2O_2 concentration was expressed as remanent active tension, % of the precontraction level. Inhibition by 4-AP (10 mM) of the relaxation induced at each H_2O_2 concentration was expressed as % of the respective relaxation in the absence of 4-AP.

All drugs were from *Sigma*. Statistics (using *GraphPad*): data expressed as mean ± SD; n=6 in each group; two-way ANOVA, multiple t-test, extra sum-of-squares F test for EC_{50} comparison; $p<0.05$ significance limit in all procedures.

This study was approved by Research Ethics Comission of the host institution.

All procedures comply with guidelines from: Act on Animal Experimentation and Animal Health and Welfare from Romania; Universities Federation for Animal Welfare; Directive 2010/63/EU of the European Parliament and of the Council of 22 September 2010.

RESULTS

Table I presents the relaxing effects of H_2O_2 in de-endothelised small mesenteric arteries of the rat, precontracted by phenylephrine 0.01 mM. H_2O_2 induced similar relaxations of rings precontracted by either norepinephrine (NE) or phenylephrine (PHE) ($p>0.05$ for all H_2O_2 concentrations tested).

Results are expressed as remanent active tension, % of the precontraction level (mean ± SD; n=6 in all cases; *$p<0.01$).

TABLE I.

Relaxing effects of H_2O_2 in de-endothelised small mesenteric arteries of the rat, precontracted by phenylephrine 0.01 mM

H_2O_2 mM	phenylephrine 0.01 mM
0.001	95.4±2.6*
0.01	86.8±3.1*
0.1	36.2±1.7*
1	12.4±2.4*

Inhibition of H_2O_2 effect in the case of NE was inhibited completely by the Kv channels blocker 4-AP (table 2; $p<0.001$ for all H_2O_2 concentrations tested). The inhibition of H_2O_2 effect by 4-AP was weaker in the case of PHE than in the case of NE (tab. II; $p<0.001$ for all H_2O_2 concentrations tested).

TABLE II.

Inhibition by 4-AP (10 mM) of the relaxation induced by H_2O_2 in de-endothelised small mesenteric arteries of the rat, precontracted by either norepinephrine 0.01 mM or by phenylephrine 0.01 mM

H_2O_2 mM	phenylephrine 0.01 mM	norepinephrine 0.01 mM
0.001	10.42 ± 1.13*	1.45 ± 2.73
0.01	11.23 ± 3.25*	5.23 ± 3.50
0.1	16.54 ± 3.21*	4.14 ± 4.26
1	25.38 ± 2.32*	5.38 ± 3.32

The inhibition by 4-AP (10 mM) of the relaxation induced at each H_2O_2 concentration was expressed as remaining % compared to the respective relaxation in the absence of 4-AP considered as 100 % (mean ± SD; n=6 in all cases); *$p<0.001$ for comparison between the effects at the same H_2O_2 concentration presented in the respective columns.

DISCUSSION

There is massive research on EDR, with sustained interest in EDH-mediated EDR, the major EDR pathway in resistance arteries (1, 2, 3, 5, 6, 11, 12, 13, 14, 20, 21, 24, 25, 26, 27, 28, 30), including the role of endothelium-derived hydrogen peroxide (H_2O_2) as EDHF (6, 13, 14, 20, 21, 24, 27). Quite many studies have tested the mechanisms for the direct relaxing effect of H_2O_2 upon VSM in various arteries and conditions and we have cited here just a few (17, 18, 19, 22, 32)

The effects of exogenous H_2O_2 may vary with the vascular bed and experimental conditions, but relaxation predomi-

nates. Various contributions of different K^+ channels and cGMP have been shown for the relaxing effect of H_2O_2 in small arteries from different species and vascular beds. We have previously shown that H_2O_2 induced similar relaxations of rings precontracted by either norepinephrine (NE) or phenylephrine (PHE), but weaker when contraction was induced by high K^+, or by NE in the presence of high K^+, or by PHE in the presence of high K^+ (17). Then we have also shown that in the case of PHE methylene blue (MEB) moderately inhibited H_2O_2 effect, high K^+ strongly inhibited it, and the combination of MEB and tetraethyl-ammonium (TEA) almost completely abolished it (17). In our earlier study TEA revealed the involvement of BKCa, in agreement with the EDHF role of H_2O_2, while MEB showed only some contribution of cGMP. Others have shown that relaxation of the similar rabbit preparation by H_2O_2 is mediated by cGMP.

In the present study, the inhibition of H_2O_2 effect in the case of NE was complete with 4-aminopyridine (4-AP), a blocker of Kv channels, as shown very recently by another group, using the same vascular preparation (22). We underline here the complexity and high quality of that study (22), which is also oriented towards the Kv implications in redox signaling, as later another group has shown that coronary microvascular Kv1 channels function as regulatory sensors of intracellular pyridine nucleotide redox potential (32). However, the relaxing effect of H_2O_2 upon VSM in other vessels, such as coronary arteries, is based on BKCa (18).

Based on our results, and also on the recent findings from other laboratories, we may conclude that in rat small mesenteric arteries the relaxation induced by H_2O_2 is mediated to a different extent by Kv and BKCa depending on the contracting agent. Ultimately, endogenous endothelium derived H_2O_2 could activate smooth muscle both K^+ channel types and thus functionally compensate for decreased NO availability.

CONCLUSIONS

It is known that EDH-mediated EDR, which is the major EDR mechanism in resistance arteries, involves endothelium-derived hydrogen peroxide as EDHF acting on BKCa in VSM. But here we confirmed that exogenous hydrogen peroxide relaxes the isolated small mesenteric arteries of the rat by involving 4-aminopyridine-sensitive Kv potassium channels in VSM.

NEWS

ONE SMALL MOLECULE FOR A MAN, ONE BIG STEP FOR CANCER RESEARCH

Triple negative breast cancer (TNBC) is known for being the most aggressive subtype of breast cancer with limited treatment options. The goal herein is to supersede common treatment approaches with novel anti-neoplastic therapies. By using nanotechnology Saraiva and colleagues encapsulated edelfosine (a lipid member of alkyl-lysophospholipid family) in a nano-emulsion and validated its anti-tumoral effects *in vitro* and *in vivo* with promising results. Incubating MDA-MB-231 cells for 24h they showed a dose-dependent cytotoxic effect compared to the control formulation, mainly by the capacity of the drug to be highly internalized by the cancer cell lines. Furthermore, using zebrafish xenografts bearing MDA-MB-231 cells they revealed a decrease in the proliferation of neoplastic cells envisioning a promising approach to TNBC treatment (Saraiva SM, Gutiérrez-Lovera C, Martínez-Val J, *et al*. Edelfosine nano-emulsions inhibit tumor growth of triple negative breast cancer in zebrafish xenograft model. *Sci Rep* 2021; 11: 9873 / doi.org/10.1038/s41598-021-87968-4).

DICLOFENAC SODIUM ENTRAPPED IN MICROPARTICLES EXHIBIT PROLONGED ANTINOCICEPTIVE EFFECTS IN HOT PLATE TEST IN RATS

DICLOFENAC SODIUM ENTRAPPED IN MICROPARTICLES EXHIBIT PROLONGED ANTINOCICEPTIVE EFFECTS IN HOT PLATE TEST IN RATS (Abstract): We **aimed** to evaluate the influence of microparticles containing DCF on the somatic nociceptive reactivity in rats. **Material and methods:** We used a novel procedure to entrap DCF in soft matter vesicles based on phosphatidylcholine and coated with chitosan. These original carrier systems were physicochemical characterized using a Malvern Zetasizer Nano ZS, ZEN-3500 apparatus. To investigate the effects of microparticles with DCF on the nociceptive reactivity, 3 identical groups of 5 white male Wistar rats each were used. The substances were administered orally (using an eso-gastric device) in a single dose according to the following protocol: Group 1 (Control): distilled water 0.3 ml/100 g body weight - control; Group 2 (DCF): 5 mg/kg body weight diclofenac; Group 3 (DCF-mp): chitosan-based microparticles entrapping diclofenac 5 mg/kg body weight. The somatic nociceptive reactivity was estimated using the hot plate model. The latency time reaction to paws noxious thermal stimulation was assessed before the experiment (baseline) and 15, 30, 60, 90, 120 minutes, 4, 6, 8, 10 hours, after the substances administration. Experimental protocol was approved, and the research were performed according to recommendations of the "Grigore T. Popa" University of Medicine and Pharmacy Committee for Research and Ethical Issues. The data were presented as +/- standard deviation and analyzed using *SPSS* for Windows version 17.0 and ANOVA one-way method. **Results:** We prepared original microparticles containing DCF of 562 ± 13.37 nm mean size, +45 ± 1.67 mV mean Zeta potential with a good stability in colloidal solution. The treatment with DCF resulted in substantial increase of the latency response, in the interval between 15 minutes and 90 minutes in hot plate test. In use of DCF-mp resulted in statistically significant increase of the latency time, between 2 and 10 hours in this somatic pain model in rats. **Conclusions:** The lipid vesicles stabilized with chitosan, as carrier for DCF, presented the advantage of a prolonged release of active substance, comparing with non-entrapped drug in hot plate model in rats. **Keywords:** DICLOFENAC, LIPID VESICLES, MICROPARTICLES, HOT PLATE, NOCICEPTION, RATS.

One of the most challenging research directions is the design and study of ways to entrap some nonsteroidal anti-inflammatory drugs (NSAIDs), agents frequently prescribed in medical practice, in various pathological conditions accompanied by

pain, fever or inflammation. The obtaining of new carrier systems incorporating NSAIDs is of great interest, in view of the fact that, these drugs are from various classes, with differences in terms of pharmacokinetic aspects, as well as with an increased risk of adverse effects in the body.

Diclofenac (DCF) is an active drug belonging to class II (according to the biopharmaceutical classification system) with a high degree of permeability, but with a low solubility (1). This phenylacetic acid derivative is structurally related and has pharmacological properties similar to mefenamic acid and sodium meclofenamate.

There is evidence that DCF inhibits the cyclooxygenases, the lipoxygenases, phospholipase A2 and activates the antinociceptive nitric oxide-guanzine monophosphate pathway. It is also speculated that it may also inhibit phospholipase A2 (2, 3). These additional actions may explain the high potency of DCF, which is known as one of the most powerful NSAIDs (4, 5).

The analgesic potency of DCF is 6 times higher than that of indomethacin, sulindac or codeine, 15 times higher than naproxen and 40 times higher than acetylsalicylic acid. It has a relatively long duration of action (6-8 hours), but a half-life of 1.5-2 hours, which is why it needs to be administered in 3-4 daily doses (6, 7).

DCF is a very good visceral analgesic, being indicated in acute, moderate and severe pain in acute and chronic cholecystitis, renal colic pain, and in dysmenorrhea, as well as in postoperative and post-traumatic pain, neoplastic pain, inflammatory or degenerative arthritis (8, 9, 10, 11, 12).

MATERIAL AND METHODS

Substances

DCF, chitosan, phosphatidylcholine, cholesterol, chloroform were purchased from Sigma-Aldrich Chemical Co. (Steinheim, Germany). The chitosan used had a degree of N-deacetylation of 79.7%, the average molecular weight was Mw = 310,000 g/mol and 3.26 polydispersity index. The 0.5% (w/w) chitosan solution was prepared in a 0.5% (v/v) acetic acid solution. The lipid used was L-α-phosphatidylcholine (egg yolk type XVI-E, 99% TLC purity). Bi-distilled water was procured from Zentiva Company, Prague, Czechia.

The preparation of lipid vesicles entrapping diclofenac

First of all, L-α-phosphatidylcholine was dissolved in chloroform and the solvent was removed by evaporation (RE-2000A Rotary Evaporator, Ya Rong Biochemical Instrument Factory, City, China). Afterward, the resulted dry lipid film was hydrated with a DCF solution in alcohol/water. The obtained solution was sonicated for 20 minutes (Sonoplus Bendeline ultrasound generator, GmbH & Co. KG Berlin, Germany). The lipid vesicles were mixed with the chitosan solution, which was thereafter dialyzed for 10 hours (dialysis tubes type D6191-25EA, with pores of 12,000 Da MWCO from Sigma Aldrich, Steinheim, Germany), to increase the pH to values close to the physiological ones.

The physico-chemical characterization of the obtained systems was assessed using a Malvern Zetasizer Nano ZS ZEN-3500 apparatus (Worchestershire, UK).

Laboratory animals

Healthy, non-genetically modified white male Wistar rats (200-250 g weight, 3 months age) were used in the research. The animals were received from the National Medical-Military Institute "Cantacuzino" for Research and Development, Băneasa Resort, Bucharest, Romania and brought to the CEMEX laboratory ("Advanced Center

for Research and Development in Experimental Medicine - CEMEX") biobase, of the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi, Romania.

Before the experiment, the animals were positioned on a raised wire mesh, under an acrylic box and allowed 2 hours to acclimate to the testing room, in normal laboratory conditions (with 55-65% relative humidity, 23.0 ± 2.0°C temperature and 12 hours light: dark cycle).

Standard laboratory standardized food (pellets) and tap water were freely available, except during the time of the experiments. To avoid chrono-biological interferences, the investigations were performed in the interval 8-12 a.m. daily.

Hot plate test

To evaluate the effects of micro nanoparticles with DCF on the nociceptive reactivity, 3 identical groups of 5 animals each were used, as follows:

- Group 1 (Control): distilled water 0.3 ml/100 g body weight - control;
- Group 2 (DCF): 5 mg/kg body weight diclofenac;
- Group 3 (DCF-mp): chitosan-based microparticles entrapping diclofenac 5 mg/kg body weight;

The substances were administered directly in the stomach (using an eso-gastric device) in a single intake. Intragastric administration was performed using a standardized polypropylene tube for rats (size no. 16-20, length 5 cm), bought from the specialized companies for laboratory supplies.

Using the experimental somatic pain model hot plate we evaluated the nociceptive reactivity, by measuring the changes in sensitivity induced by the test substance, when thermal stimuli were applied on the paws (13, 14, 15). This test assessed the animals reaction time when was placed on a hot plate heated to 52°C (PanLab Harvard Apparatus hot-plate device). The measurement of the latency period of the response to nociceptive paw thermal stimulation was performed before (baseline), at 15 minutes, 30 minutes, 60 minutes, 90 minutes, 2 hours, 4, 6, 8, respectively 10 hours after the administration of the substances. The maximum exposure time to the thermal stimulus (cut-off time) was established for 12 seconds, in order to prevent the paws damage.

To quantify the intensity of antinociception, latencies are converted into percentages of the maximum possible effect (%MPE) (16, 17, 18):

$$\%\ MPE = (measured\ latency - baseline\ latency) \times 100 / (cut\ off\ time - baseline\ latency)$$

The changes in the pain threshold produced after the administration of the microsystems containing DCF, were considered relevant above 60% MPE, because the values below 60%, although they may have statistical significance, the biological one is questionable.

In this somatic pain model, the prolongation of the reaction time compared to the values obtained before the administration of the tested substances, corresponds to an antinociceptive effect of the studied substances. The shortening of the latency period of the response signifies a hyperalgesic effect of the investigated substances.

Statistical analysis

The obtained results were presented as mean values ± standard deviation of the mean (S.D.) of the latency period of the response to the painful thermal stimulus, at each time point and for each studied substance. The data were centralized, and statistically processed, using the *SPSS 17.0* software for Windows EXCEL, and the ANOVA one-way method.

Ethical aspects

The study was approved by the Ethics

Committee of "Grigore T. Popa" University of Medicine and Pharmacy, Iasi (Certificate No. 24/21.12.2020). The experimental protocol was conducted in agreement with the standards of the International Association for the Study of Pain (19), and the European regulations concerning the handling of laboratory animals (20).

RESULTS

Physico-chemical characterization of DCF-mp

Lipid microvesicles entrapping DCF, based on phosphatidylcholine and coated with chitosan were prepared. The measurements revealed that the DCF-mp have a mean size of 562 ± 13.37 nm, with a polydispersity index of 0.189.

As nanomaterials are defined as structures possessing, at minimum, one external dimension measuring 1-100 nm (21), the current lipid vesicles entrapping DCF stabilized with CHIT, having mean size 562 ± 13.37 nm, were considered to be microparticles.

The vesicles in colloidal solution have a mean Zeta potential of +45 ± 1.67 mV, which indicated their good stability.

Hot plate test

The analysis of the data obtained at different moments of time, in the dynamics of the hot plate test, reveals the following:

- the treatment with DCF was associated by a considerable increase (**p<0.01) in the response latency period, compared to the control group from 15 minutes to 90 minutes in the experiment;

- the highest latency of the response (7.58 ± 0.12 seconds) to the application of painful noxious stimulation on the paws was observed at 60 minutes in the experiment.

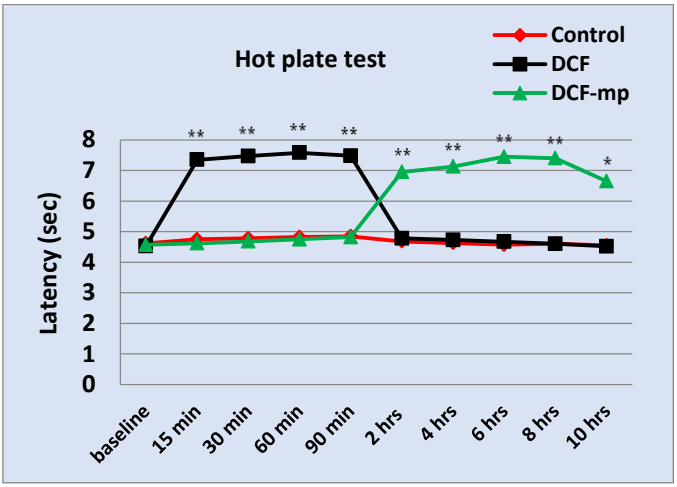

Fig. 1. The influence of DCF and DCF-mp on the nociceptive reactivity in hot-plate test in rats.

The data are presented as arithmetic mean ± S.D. of mean latency time response for five rats in a group. **p<0.01, *p<0.05 were considered statistically significant versus control.

- the administration of vesicles carrier incorporating DCF was associated with prolongation of the latency period of the

response to thermal stimulation of paws, statistically significant (**p<0.01) compared to distilled water group, in the time interval between 2 and 8 hours, with a highest value at 6 hours in the experiment (7.45 ± 0.05 seconds). The effect was maintained significant (*p<0.05) also at 10 hours in this somatic pain model in rats.

- the delay in the manifestation of the effect may be due to the particularities of the DCF release from the soft lipid vesicles stabilized with chitosan.

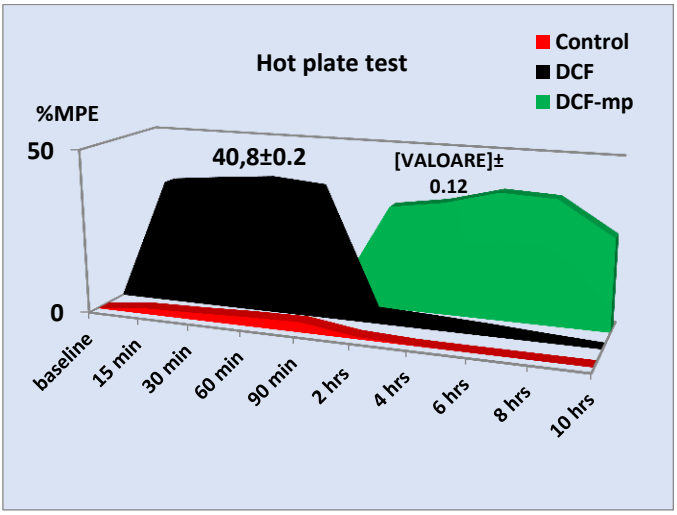

Fig. 2. Quantification of the intensity of the analgesic effect produced by DCF and DCF-mp in the hot plate test in rats**.**

The quantification of the intensity of the analgesic effect in the hot plate test highlighted that:

- the maximum analgesic effect (%EMP) produced by DCF alone or incorporated in soft lipid vesicles, was below 60% at any time moment of the determinations.

- the use of DCF resulted in an increase in % MPE statistically significant in the first 90 minutes with the peak effect noted after 60 minutes (%EMP = 40.8 ± 0.2) in the experiment.

The data are presented as arithmetic mean ± S.D. of mean %MPE for five rats in a group

- the oral administration of microparticles with DCF induced a significant increase of antinociceptive effects, in the interval between 2 hours and 10 hours.

- the treatment with DCF-mp induced a maximum possible effect of analgesia at 6 hours in the experiment (%EMP = 38.8 ± 0.12).

DISCUSSION

A modern and interesting direction of research is the design and study of ways to incorporate non-steroidal anti-inflammatory drugs (NSAIDs), agents frequently prescribed in medical practice for various diseases accompanied by pain, fever or inflammation (8, 9). The phenylacetic acid derivative diclofenac is a NSAIDs with potent anti-inflammatory activity but also with a high risk of gastric irritation (9, 22). In order to reduce the number of admin-

istrations of such a drug, with a short half-life, there is a need to obtain sustained-release systems, formulations, whose oral use could diminish the adverse gastrointestinal effects (6, 7).

Lipid-based formulations have been shown to significantly improve the bioavailability of hydrophobic drugs such as diclofenac compared to conventional dosage forms (23, 24, 25).

Lipid vesicles composed mainly of phospholipids and cholesterol. They are spherical in shape, composed of an internal aqueous compartment surrounded by a variable number of lipid bilayers. The formation of these systems is a spontaneous process that occurs when mixtures of phospholipids with cholesterol and/or other amphiphilic molecules are hydrated. Phospholipids form vesicles due to the hydrophobic effect of their acyl chains in the aqueous environment. The bonds involved are hydrogen bonds, Van der Waals forces or other electrostatic interactions (26).

Hydrophobic molecules are inserted into the bilayer membrane and hydrophilic molecules can be trapped in the aqueous center (27). As drug delivery systems, liposomes offer several benefits, including biocompatibility, self-assembly capability, capacity to carry large drug payloads, and a wide range of physicochemical and biophysical properties that can be modified to control biological characteristics (28, 29).

Liposomal formulations are characterized by properties such as particle size, charge, number of lamellae, lipid composition, and surface modification with polymers and ligands-all of them confer stability in vitro and also *in vivo* (30). The mucus covering the surface epithelium of the gastrointestinal tract possesses an adsorbent layer of phospholipids, which creates a hydrophobic zone between the epithelium and the luminal contents. At this level there are a number of lipid species reminiscent of surface-active phospholipids, of which phosphatidylcholine is suitable to incorporate diclofenac. It has been shown that in the presence of the ionic surfactant shield, the complex remains lipophilic (31).

Among all nanoparticulate systems, lipid vesicles have several advantages, represented by the low number of excipients required for their formulation, the simple preparation procedure, a high physical stability and the possibility of sustained drug release, which could be used in the treatment of various pathological conditions (25, 32).

The incorporation of drugs in organized structures is of great interest, especially in terms of absorption and targeted action in the body. It has been suggested that encapsulation with the help of phospholipids is one of the ways to improve these pharmacokinetic and pharmacodynamics aspects, but also that the drug can cause the structural modification of phospholipids, with the formation of surface-active monomers (33, 34, 35).

In our experimental research a novel micro-system entrapping DCF inside soft matter vesicles were prepared.

The use of DCF was accompanied by a rapid and progressive prolongation of the latency period of the paws withdrawal response to thermal noxious stimulation, with a statistical relevance between 15 minutes and 90 minutes, with a maximum value after one hour in the experiment, this result being in concordance with the literature information about the antinociceptive effects of this NSAID in hot plate test in rodents (36, 37).

The treatment with DCF entrapped in

microparticles was followed by significant antinociceptive effects, which have begun after 2 hours, with a maximum intensity at 6 hours, and extended around 10 hours after the administration. It is possible that the 2-hour delayed onset of the analgesic effect is due to the release after a period of latency of the active substance from the chitosan-stabilized lipid vesicles.

CONCLUSIONS

The new designed microparticles containing DCF demonstrated significant and sustained analgesic effects in hot plate test in rats.

In our experimental conditions, we demonstrated that, the use of lipid vesicles stabilized with chitosan, as carrier for DCF, presented the advantage of a prolonged release of active substance, comparing with non-entrapped drug in this cutaneous pain model in rats.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest.

NEWS

THE GLOBAL CHALLENGE OF COLISTIN RESISTANCE- RECENT EVIDENCE FROM ROMANIA AND ELSEWHERE

The increasing resistance of Gram-negative bacilli to a wide range of antibiotics has driven a return to colistin as the last resort in the treatment of severe infections. Given the stakes of colistin efficiency at both the individual level and generally, the manifestation and mechanisms of resistance to polymyxin E (also known as colistin) are now subject to careful monitoring and research. Recent findings from different parts of the world including Romania are reviewed and discussed in light of ensuing challenges. The increasing prevalence of multidrug-resistant strains has substantial, far-reaching negative implications for the entire world. The still excessive use of antibiotics and their diminishing effectiveness can limit treatment options to colistin, which we now know is not invulnerable. Invasive medical procedures and prolonged hospitalization can further contribute to the risk of developing resistance to this life-saving medication. In countries like Romania, where data is still scarce but sufficiently concerning, more research and communication need to be conducted with an adequate sense of urgency (Vlad MA, Ursu RG, Iancu LS, *et al*. The Global Challenge Of Colistin Resistance - Recent Evidence from Romania and Elsewhere. *Biomed J Sci&Tech Res* 2021; 40(1): 31950- 31952).

CORRELATION BETWEEN KIDNEY AND LIVER IMPAIRMENT WITH OUTCOME IN LIMB VASCULAR TRAUMA

CORRELATION BETWEEN KIDNEY AND LIVER IMPAIRMENT WITH OUTCOME IN LIMB VASCULAR TRAUMA (Abstract): Vascular trauma represents one of the most challenging surgical emergencies. The management starts in the prehospital phase and is completed by the intervention of the vascular surgeon. Vascular trauma has a high mortality and morbidity rate, depending on the type of mechanism, localization and associated lesions and it is frequently associated with long term complications. **Material and methods**: This paper includes 146 consecutive patients with limb trauma admitted to the Department of Vascular Surgery of the "Sf. Spiridon" County Clinical Emergency Hospital, between 2011 and 2022. From the total number, 79.59% were male patients, 73.28% from rural area, mean age 45 years old. **Results:** The most frequent trauma involved the upper limb with 93 cases (brachial artery - 51 cases, axillary artery - 23 cases), followed by lower limb with 54 cases. Thirty-four cases had vascular lesions involving the nerves and 47 cases were associated with venous lesions. The most frequent mechanism was penetrating lesions via stabbing or cutting (59.59%). Intra operatively, the following procedures were performed: simple exploration and hemostasis, end-to-end anastomosis, interpositions, and bypass. Seventeen patients required amputation, and 10 had decompression fasciotomies. **Conclusions:** The prolonged time of ischemia (> 6 hours), hemorrhagic shock, reperfusion syndrome with renal or hepatic impairment are highly correlated with an increased risk of amputation and mortality. **Keywords:** VASCULAR TRAUMA, ACUTE ISCHEMIA.

Vascular trauma represents one of the most challenging surgical emergencies for the vascular surgeon because the outcome is very much time dependent. The management of trauma patients starts in the prehospital phase and is completed with the revascularization of the affected segment. There are two therapeutic management musts: first, to achieve hemostasis and secondly, to perform reconstruction of the injured artery and through that to ensure remission of the acute ischemia (1). Vascular trauma has a high mortality and morbidity rate (50-60%) (2), depending on the type of mechanism, localization and secondary lesions, and it is frequently associated with long term complications.

Vascular injury has a higher incidence

in younger patients and has a high impact on years of productive life lost (YPLL). This index is directly correlated with disability secondary to limb amputation or the loss of limb functionality contributing to increasing the number of young patients unable to work. YPLL is higher in trauma compared to deaths caused by cancer or cardio-vascular pathologies. For every traumatic death, the average YPLL is 36 years compared with 16 years for cancer and 12 years for cardio-vascular disease.

In Romania, statistic data on vascular trauma are limited and outdated.

MATERIAL AND METHODS

We included 146 consecutive patients with limb trauma admitted to the Department of Vascular Surgery from "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, between 2011 and 2022. Patient demographics, time from injury to hospital, clinical presentation aspects, biological parameters, management, intraoperative findings and evolution were analyzed in a retrospective fashion. All data were recorded and were statistical analyzed using *Microsoft Excel* and *SPSS* software. Chi square descriptive test was used to identify correlations between patient evolution and type of lesion or biological parameters at admission in the attempt to prove that patients with prolonged time of ischemia, with extensive lesions and critical biological parameters have poor outcome. End point evolution parameters were limb salvage and mortality. A p-value < 0.05 was considered significant.

RESULTS

In our study the prevalence of male patients (79.59%), majority coming from rural area (73.28%), with an age median of 45 years, and 115 patients were active workers, raising the potential impact of trauma on YPLL.

With a median of 12 patients with vascular trauma/year the Department of Vascular Surgery "Sf. Spiridon" County Clinical Emergency Hospital from Iasi can be considered an important vascular trauma center. Majority of patients (N=50; 34.24%) were from Iasi, but the addressability was from all over Moldova region (Bacău, Botoșani, Galați, Iași, Neamț, Suceava, Vrancea and Vaslui counties).

Study group general information are summarized in first table.

Trauma mechanisms were diverse, 59.59% of the vascular lesions were caused by penetrating injuries (stabbing /cuts), the rest were due to polytrauma, crush and car accidents, or following dislocations and fractures. 2 cases of iatrogenic lesion caused by catheterization were documented (fig. 1).

There is a higher percentage of the vascular trauma in the upper limb, more frequently affecting the brachial artery (51 cases), axillary artery and its branches (28 cases), comparing with lower limbs vascular trauma, with vascular lesions more frequently affecting the popliteal artery (21 cases) (fig. 2).

In 34 cases there were also major nerve lesions and in 47 cases venous lesions. In all cases, the deep vein was ligated, while neurorrhaphy was performed in 30 cases. 9 out of 10 cases with injury of the entire vasculo-nervous bundle were at the brachial level.

Patients underwent surgical artery repair via one of the following procedures: patch-plasties with autologous graft, end-to-end anastomosis, interpositions or bypass (fig. 3). Patients that required primary amputation, without an attempt of limb salvage due to mangled extremity were excluded from the study.

TABLE I
Patient general information

Patient characteristics		Number	Percent (%)
Sex			
	M	116	**79.59%**
	F	30	20.41%
Age (years)			
	median	45	-
	≤ 17	3	2.05%
	18-45	77	**52.73%**
	46-65	38	**26.02%**
	≥ 66	27	18.49%
Provenience			
	R	107	**73.28%**
	U	39	26.72%
Affected limb

	Artery	122	**83.56%**
	Vein	47	32.19%
	Nerve	34	23.28%
Time from injury			
	First 6 hours	123	**84.25%**
	Between 6-24 hours	12	8.22%
	More than 24 hours	11	7.53%

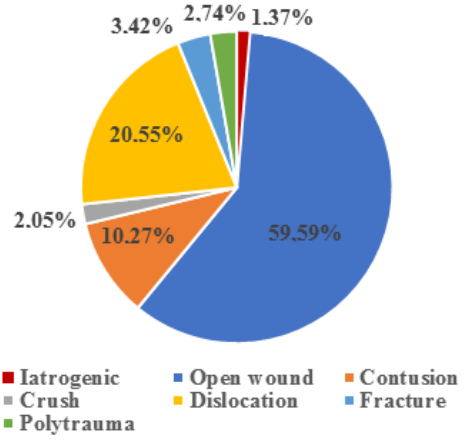

Fig. 1. Types of trauma mechanisms in the study group

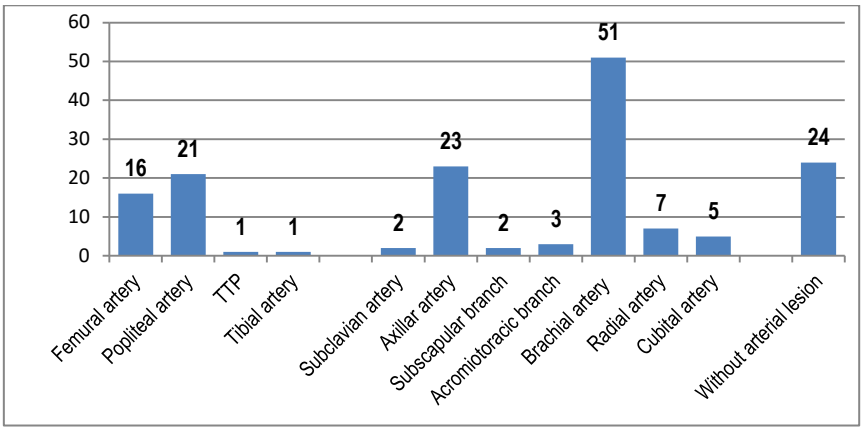

Fig. 2. Injured artery

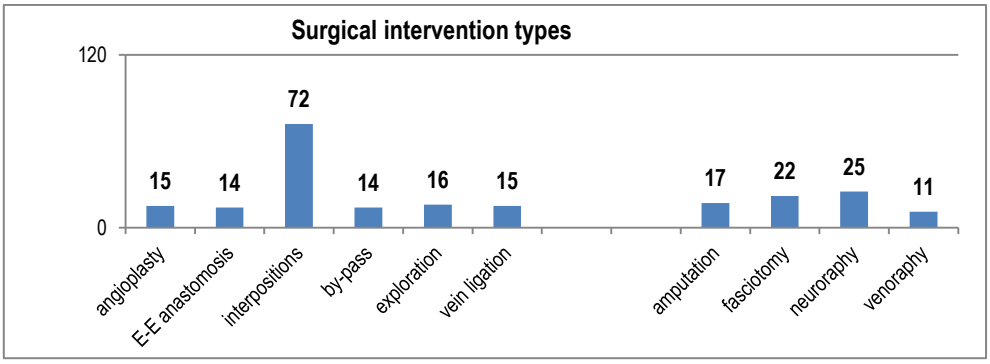

Fig. 3. Types of surgical intervention

84.83% patients had favorable evolution with peripheral pulse. Patients that underwent amputation (11.03%) or died (4.10%) were considered to have unfavorable evolution. The death causes were multiple organ failure (3 cases) and hemorrhagic shock (3 cases).

We identified correlations between patients with reperfusion syndrome, who needed fasciotomy and patients who later suffered above knee amputation ($p<0.05$). Out of 17 patients with amputation 10 had previous fasciotomies. Regarding the evolution, there was no correlation with the trauma mechanism or the affected limb (upper or lower), but the more proximal the artery was affected, the higher the risk for amputation and mortality.

The time from the traumatic event until presentation (from index symptom to surgery) and revascularization was noted. Most patients were admitted within the first 6 hours from index symptom to surgery. Higher risk of amputation and death was noted in those patients that had prolonged time of hemorrhage or ischemia ($p<0.001$) (tab. II).

We identified strong correlations and unfavorable evolution in patients with both kidney and liver impairment ($p<0.001$). Creatinine higher than 35 mg/dL and urea higher than 1.3 mg/dL are signs of kidney impairment. For the liver function the

transferases values and creatine kinases (CK) were being analyzed, the cut off values being 100 U/L, respectively 250 U/L (tab. III). CK elevated values were also a sign of poor outcome and were independently correlated with unfavorable evolution (p=0.002) (tab. III).

Organ failure as a consequence of both prolonged ischemia and reperfusion as conjunct mechanisms or independently.

TABLE II.

Correlation between time and evolution

		EVOLUTION		PATIENTS
		unfavorable	favorable	
TIME	>6 hours	8 (5.47%)	13 (8.90%)	21 (14.38%)

DISCUSSION

In this group almost 24% of the vascular lesions were a consequence of dislocations and fractures. The real percentage is higher. The group was formed only from patients admitted in the Vascular Surgery Department leaving out a part of the patients that had type III C fractures usually admitted in the Orthopedic Department. The study group can be extended and reviewed after the inclusion of those patients.

Vascular Surgery Department from “Sf.

Spiridon" County Clinical Emergency Hospital from Iasi is the single most important trauma center in the region of Moldova and a reference center for vascular trauma. At the same time, it highlights the insufficient vascular surgeons in the region that can be a cause of delayed intervention on vascular trauma patients. The median of 12 patients/year is comparable with other notable vascular surgery centers(i.e. At a university teaching hospital in Australia, Tobin (3) reported 10 cases per year of extremity vascular injuries; in Tbilisi, Georgia, Razmadze (4) reported 10.5 cases per year; in Sweden, Kjellstrom and Risburg (5) reported 8.2 cases per year; and in Oxford, United Kingdom, Magee *et al*. (6) reported 4.7 cases per year), but the injury mechanisms are markedly different from those reported all around the world (6). Most of the traumatic lesions were due to stabbing or agricultural accidents while in other countries the main cause of trauma are car accidents or gun shots. Being mainly a consequence of agricultural accidents, this can be an explanation why the involvement of the upper limb is higher. This aspect is particular to this study, literature mostly reports lower limb trauma (7).

CONCLUSIONS

The prolonged time of ischemia (> 6 hours), hemorrhagic shock, reperfusion syndrome with renal or hepatic impairment are highly correlated with an increased risk of amputation and mortality.

The management of patients with traumatic vascular lesions is challenging, involving a multidisciplinary approach (vascular surgeon, emergency doctor, anesthesiologist, orthopedic surgeon and plastic surgeon). Reducing ischemia time by addressing the patient rapidly to the vascular surgeon is mandatory. More centers of vascular surgery have to be established all over Moldova region in order to reduce the transportation time and improve the patient survival rate and limb salvage prognostic.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

CORRELATIONS BETWEEN THE LYMPHOID INFILTRATE AND THE STEROID HORMONE RECEPTORS IN ENDOMETRIOSIS (Abstract): **Aim**: Endometriosis, a chronic estrogen-dependent disease, is associated with persistent pelvic pain and is classified as a neuro-inflammatory disorder. This study aimed to decipher the inflammatory milieu in endometriosis, focusing on the lymphoid infiltrate represented by the CD4+ cells, CD8+ cells, and CD68+ macrophages, and the possible correlation with steroid hormone receptor expressions. **Material and methods**: Research conducted at the "Elena Doamna" Clinical Hospital and the "Grigore T. Popa" University of Medicine and Pharmacy in Iaşi, Romania, involved retrospective analysis of 53 patients with endometriosis from 2018 to 2023. **Results:** Through immunohistochemical assays, we observed correlations between CD4 and CD8 expressions, and between CD4, CD68, and the PR score. Also, a possible causality between the macrophage infiltrate and PR expression could be suggested. **Conclusions:** The inflammatory infiltrate's analysis in endometriosis provides a deeper knowledge of its pathological development and the interplay of inflammatory cells. Understanding these receptors might guide future treatment strategies for better disease management. **Keywords:** ENDOMETRIOSIS, INFLAMMATION, LYMPHOID INFILTRATE, STEROID HORMONE RECEPTORS.

Endometriosis is a chronic, estrogen-dependent disease characterized by the ectopic growth of endometrial tissue (encompassing both glands and stroma) outside the uterine cavity. This pathology is frequently correlated with persistent pelvic pain and is contemporarily classified as a neuro-inflammatory disorder (1).

The etiopathogenesis of endometriosis has been extensively studied, yet definitive understanding remains evasive. We currently have data about the roles of genetic predisposition, estrogenic modulation, progesterone resistance, and inflammatory pathways, in conjunction with altered expression of hormonal receptors such as estrogen receptors (ER) and progesterone receptors (PR) (1, 2). Immunological components are hypothesized to be instrumental in both the inception and evolution of

endometriosis (3-5).

Within the inflammatory cellular milieu associated with endometriosis, CD4+ T cells and CD8+ T cells are discernible, albeit their precise pathological roles remain only partially delineated (6). Concurrently, macrophages are posited to be pivotal in the proliferation, angiogenesis, innervation, and nociception of endometriotic lesions (7-10).

The heterogeneity of the intralesional inflammatory infiltrate across various histological manifestations of endometriosis holds potential for profound insights into the sequential pathophysiological events and the multifaceted immune responses in endometriosis (11). Our study seeks to elucidate the composition of the inflammatory milieu through a semi-quantitative analysis of CD4+ cells, CD8+ cells, and CD68+ macrophages in ovarian and cutaneous endometriosis. Complementarily, we assessed the immunohistochemical expressions of estrogen and progesterone receptors, trying to find correlations and eventual causalities.

MATERIAL AND METHODS

The research was undertaken at both the "Elena Doamna" Clinical Hospital and the "Gr. T. Popa" University of Medicine and Pharmacy located in Iași, Romania. This study encompassed a retrospective review of clinical records combined with histopathological examinations of surgical samples (ranging from nodule removals to full hysterectomies with adnexectomy) from 53 patients diagnosed with endometriosis between the years 2018 and 2023.

Slides stained with Hematoxylin-Eosin (HE) were viewed by a pair of independent pathologists to verify the diagnosis. An immunohistochemical (IHC) test followed, utilizing specific antibodies (tab. I). Upon completion of the IHC procedure, a semi-quantitative evaluation of the immunoreactivity of the inflammatory infiltrate in the epithelium and stroma has been carried out. Also, the ERα and PR quantification used a score based on the positivity index added to the staining intensity. The analysis has been performed using their respective scores available in literature (12-16).

TABLE I.
Antibodies used in the immunohistochemical assay

Antibody	Type	Clone	Dilution
CD4	Mouse Monoclonal	4B12/Novocastra	1/100
CD8	Mouse Monoclonal	1A5/Novocastra	1/50
CD68	Mouse Monoclonal	KP1/Novocastra	1/400
ERα	Mouse Monoclonal	6711/Novocastra	RTU
PR	Mouse Monoclonal	312/Novocastra	RTU

In our statistical analysis, we employed the Hoeffding measure, a non-parametric statistical method tailored for assessing the correlation between two random variables. The Hoeffding correlation measure is adept at detecting both linear and non-linear associations, useful in situations where relationships between variables might not always adhere to a linear paradigm. The Hoeffding's D measure offers a robust quantification of association without being confined to a specific form or pattern of

relationship between the variables under investigation.

We also utilized the Pearson correlation coefficient, a widely recognized parametric statistical method that quantifies the linear relationship between two continuous variables. The Pearson test measures the strength and direction of the linear relationship, providing a coefficient value between -1 and 1. A value closer to 1 implies a strong positive linear relationship, a value closer to -1 indicates a strong negative linear relationship, and a value near 0 suggests no linear correlation. Given its sensitivity to linear associations, this test is pivotal when aiming to ascertain direct proportionality or inversely proportional relationships between variables.

Informed consent was secured from all the patients, adhering to guidelines that guarantee participants make well-informed decisions and that their rights are safeguarded (17). The study received approval from the Research Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy Iasi (Approval No. 285/26.03.2023), in alignment with the Declaration of Helsinki's principles concerning medical research involving human participants.

RESULTS

The results were expressed as CD4 percent, CD8 percent, CD68 percent, ERα score and PR score. In order to investigate an eventual reciprocal influence of inflammation and hormonal imbalance in the endometriotic lesions, we performed a Hoeffding and also a Pearson test (figs. 1, 2). Both methods were used in order to compare their results, but also to capture both linear and potentially non-linear relationships.

	CD4 percent	CD8 percent	CD68 percent	ERα score	PR score
CD4 percent	1.000000	0.058491	0.014912	0.007265	-0.006719
CD8 percent	0.058491	1.000000	-0.009299	-0.007093	0.005025
CD68 percent	0.014912	-0.009299	1.000000	-0.003800	0.038728
ERα score	0.007265	-0.007093	-0.003800	1.000000	0.001113
PR score	-0.006719	0.005025	0.038728	0.001113	1.000000

Fig. 1. *Hoeffding correlation* coefficient regarding the association between lymphoid infiltrate and steroid hormones expressions

	CD4 percent	CD8 percent	CD68 percent	ERα score	PR score
CD4 percent	1.000000	0.533522	0.338297	0.108531	0.158922
CD8 percent	0.533522	1.000000	0.247454	0.143872	-0.190404
CD68 percent	0.338297	0.247454	1.000000	0.106933	0.300278
ERα score	0.108531	0.143872	0.106933	1.000000	0.220835
PR score	0.158922	-0.190404	0.300278	0.220835	1.000000

Fig. 2. *Pearson correlation* coefficient regarding the correlations between lymphoid infiltrate and steroid hormones expression

The non-linear correlation coefficient suggested a potential relationship between the expressions of CD4 and CD8, as well as the expressions of CD4 and CD68 and between CD68 and PR score. No correlation was found between CD68 and ERα expression, or between CD4, CD8, and hormonal receptors in the analyzed samples.

While correlation between random variables does not imply nor reveal causal directionality, this can be assessed with the help of an Additive Noise Model (ANM) (18, 19). We made use of the popular WhyPy Python packages to estimate through both Maximum Likelihood and Independence of Residuals the potential causal directionality for pairs of correlated variables in our data.

The ANM study results of CD4 (X0) and CD8 (X1) data are shown in figures 3 and 4. These results indicated that the box plots describing noise distribution in the modelling of dependencies X0~f(X1) and X1~f(X0), respectively, mostly overlap in both Maximum Likelihood (fig. 3) and Independence of Residual (fig. 4). These results did not support any clear causal directionality hypothesis.

Similarly, the ANM study of CD4 (X0) and CD68 (X1) revealed overlapping noise distributions as shown in figures 5 and 6, which is not indicative of any potential causal directionality.

Finally, the results of the ANM study of CD68(X0) and PR Score (X1) are shown in figs. 7 and 8. The Maximum Likelihood test shown in figure 7 supported a hypothesis for causal direction in which CD68 causes PR Score, while the Independence of Residuals test (fig. 8) does not result in clear support for either direction. Should a causal link exist between CD68 and PR Score, indicates that it is more likely that the first causes the second (fig. 7).

DISCUSSION

A key role in the pathogenesis of endometriosis is attributed to the menstrual reflux of endometrial tissue (including stem cells) into the peritoneal cavity. Nevertheless, this phenomenon is not sufficient for the development of the disease, and the microenvironment factors that stimulate the functions of stem cells and allow the development of endometriotic implants are very important adjuncts to the mechanism of retrograde menstruation (20). Also, considering the widespread distribution of endometriosis localization in the human body, modern theories attempt to combine the effect of several factors that contribute to its development, as multifactorial, multicompartmental pathogenic phenomena such as estrogen dependence, progesterone resistance, genetic susceptibility, all under the influence of environmental factors (11). Furthermore, the pathogenic mechanisms are added to the immune system's inability to neutralize ectopic endometrial cells. Additionally, the interplay between hormonal levels, inflammation, and the progression of the disease has been extensively researched.

Since 1987, Halme *et al.* proposed an immunological aspect to endometriosis (21). They observed elevated levels of activated macrophages, belonging to the cellular component of the innate immune system, in both the peritoneal fluid and the intact endometrial tissues (referred to as eutopic endometrium) of endometriosis patients compared to women without the condition (21). Given that macrophages, which have widespread tissue presence, play a pivotal role in many inflammatory and cancer-related diseases (22), they are believed to be crucial in influencing various aspects of endometriosis. This includes the growth, development, vascularization, and nerve supply of endometriotic lesions, and even in the creation and sensation of pain (7-9).

Studies on the inflammatory cell types found in the female reproductive tract have produced varied and sometimes incon-

sistent findings (3, 5, 23). These discrepancies might be due to the changing nature of the menstrual cycle, as well as the ongoing morphological shifts in both the epithelial layer and stromal regions during different menstrual phases. However, the most commonly identified immune cells in this region include T cells, macrophages, dendritic cells, NK cells, neutrophils, and mast cells (24). Accordingly, it is considered that immune cells, such as NK cells, macrophages, dendritic cells, and neutrophils, may be involved in growth, angiogenesis, and invasion processes of endometriotic cells (24). Interestingly, B cells appear to be relatively rare in the female reproductive tract (25).

A key aspect of endometriosis pathogenesis is now considered to be linked to pelvic inflammation, but the exact pathways are yet to be determined. Several research studies have shown that cells like macrophages, lymphocytes, endometrial, and mesothelial cells can produce cytokines and inflammatory agents that further attract a variety of cells, including macrophages, lymphocytes, eosinophils, mast cells, and endometrial cells to the peritoneal cavity (25). This recruitment initiates a series of reactions that stimulate the proliferation of endometriotic cells. It appears to also promote their attachment to abnormal sites, blood vessel formation, and triggers the release of additional cytokines and chemokines, intensifying their overall impact.

Moreover, growing evidence admits that endometriosis is linked with an autoimmune status (24, 26), explained by the endometriosis-induced inflammation, leading to a deregulated immune response which may induce autoimmunity (26).

The endometriosis environment is also influenced by cytokines and defensins secreted by immune cells. In this regard, the levels of immune checkpoint inhibitors, which control the immune response, are different in endometriosis than those observed in healthy women (24).

Lymphocytes play essential roles in the process of survival, implantation, and proliferation of endometrial and endometriotic cells and numerous studies have shown aberrant functions of these cells in women with endometriosis. In this regard, recent research indicates a particular association of CD4+ T cells and CD8+ T cells with endometriosis (6). There is ongoing debate on whether changes in these cells are cause or a result of endometriosis.

CD4+ T lymphocytes are often referred as T helper cells because they aid to orchestrate and amplify the immune responses by interacting with other immune cells and releasing cytokines. CD4+ T cells can differentiate into various subsets (including Th1, Th2, Th17, and T regulatory (Treg) cells), depending on the cytokine milieu, each subset playing a unique role in immune responses.

CD8+ T lymphocytes (cytotoxic T cells) have the ability to recognize antigens presented by MHC class I molecules, which are present on almost all nucleated cells. CD8+ T lymphocytes provide immunosurveillance by constantly screening host cells for intracellular pathogens or malignancies.

Our study indicates that there is a weak correlation between the number of CD4+ T cells and CD8+ T cells in the endometriotic tissue. In contrast, other recent studies have found that the CD4/CD8 ratio in the peritoneal fluid leans towards CD8+ T cells, the preponderance of CD8+ T cells being comparable to the eutopic endometrium (28). Also, CD8+ T cells in the peritoneal fluid showed higher relative frequencies when contrasted with the peripheral blood (28).

It is considered that the endometriotic altered immune response may be correlated to damaged apoptotic processes. One study revealed in healthy women increased serum concentrations of HLA-DR- activated T cells and of CD8+ T lymphocytes throughout the luteal phase in comparison with the follicular phase (29). Contrary, in endometriosis there are no fluctuations in the peripheral blood concentrations of activated and cytotoxic lymphocytes during the menstrual cycle (26, 29).

Despite the identified correlation between the two cell populations, it is difficult to propose a hypothesis for causal direction in the endometriosis scenario. Our data suggests that the relationship between CD4+ and CD8+ T cells is multifaceted. Rather than a simple cause-and-effect manner of function, they are part of a complex immune network. Their collaboration is vital for a coordinated immune response.

Thus, T cells do not operate in isolation from the environment, their changes being able to play a role in the etiopathogenesis of endometriosis. Moreover, the immune status in endometriosis is largely regulated by epigenetic factors (26, 30).

Regarding the macrophage population, outlined in our study by the CD68 expressing cells, it is well-known that in women with endometriosis they consistently represent the majority of peritoneal immune cells throughout the menstrual cycle, accounting for 55%, with T cells following at 20% (28). The elevated counts of activated macrophages and adaptive immune cells, including T and B lymphocytes, coupled with the rise in inflammatory cytokines observed in patients with endometriosis, suggest the presence of an underlying immunological/inflammatory imbalance (31). Our results suggest that there is also weak correlation between the number of CD4+ T cells and CD68 cells in the endometriotic tissue, confirming the complex and intricate roles of the two types of cell populations and giving rise to hypothesis about their reciprocal influence. On the other hand, the ANM study of CD4 and CD68 revealed overlapping noise distributions, making it impossible to indicate any potential causal directionality at the moment.

Regarding the steroidal hormones in relation to the inflammatory microenvironment, reciprocal influences could be considered to form vicious cycle, as the presence of endometriotic implants boost the expression of ER-β while decreasing PR (32-35), triggering the production of genes responsible for various inflammatory mediators like IL-1 β, IL-6, IL-8, IL-17, TNF-α, and COX-2 (10, 11). On the other hand, the chronic inflammation accelerates the aromatase activity, causing an upsurge in estradiol levels (10).

However, hormonal imbalances play a crucial role in the endometriosis etiopathogenesis, the disease being considered as a progesterone (P4)-resistant and estrogen dependent process (26, 33).

A recent study by Hogg and associates emphasizes the relationship and the reciprocal influences between the macrophages and the steroidal hormones, describing that in the presence of estrogen, macrophages enhance their proliferative ability and become activated, transitioning to a phenotype more akin to a “wound healing” population (27, 28). Also, while endometrial macrophages don’t display the progesterone receptor (36), their gene expression markedly changes in reaction to progesterone (37), indicating an indirect mode of regulation.

In the present study, no correlation was found between CD68 and ERα expression, possibly to the limited sample size or possibly due to the polymorphism of the estro-

gen receptors. Nevertheless, our analysis of the CD68 and PR score quantifications suggest a correlation between the two. Moreover, the Maximum Likelihood test shown supported a hypothesis for causal direction in which the presence of macrophages (reflected by the CD68 percent) causes a rise in the PR score.

On the other hand, current research indicates that endometriosis commonly exhibits progesterone resistance due to diminished PR expression and functionality and there is notable dysregulation of PR expression and activity in target cells, both in eutopic and ectopic tissues, when compared to standard endometrium (38). These differences might arise from the polymorphism of PR, as PGR-B is generally considered to be the positive regulator of the effects of progesterone, and PGR-A has an inhibitory effect on PGR-B (38).

Also, some differences of opinion could be generated by the main limitation of our study, its reliance on observational analysis with a limited sample size (53 cases only). In this context, the authors were found to be in the impossibility to address potential confounders, leaving room for potential bias.

CONCLUSIONS

The analysis of the chronic inflammatory infiltrate in endometriosis offers a deeper knowledge of its pathological evolution and inflammatory cell interactions. As understanding these receptors is pivotal in ongoing research, future endometriosis treatments may focus on them for an improved disease management.

It is difficult to propose a hypothesis for causal direction regarding the CD4+ and CD8+ T cells, in endometriosis. The relationship between the two types of lymphocyte is multifaceted and cofactors that contribute to their tissular and humoral activity need to be further studied and taken into account. The present data shows that while both cell types communicate and influence each other, it is not a linear, one-to-one causation.

Our findings also indicate a weak correlation between the counts of CD4+ T cells and CD68 cells in endometriotic tissue. This underscores the intricate and multifaceted functions of these two cell types and prompts speculation regarding their mutual impact.

Also, our evaluation of the CD68 and PR score quantifications indicates a relationship between them, our evidence favoring a hypothesis where an increase in macrophages (as indicated by the CD68 percentage) leads to a heightened PR score.

Our data could lay the foundation for new treatment approaches, either in the development of macrophage-targeting medications or by developing methods to overcome resistance to progestin treatment.

There is still limited data regarding the immune landscape of endometriosis. To better understand the pathogenic mechanisms of endometriosis, a more comprehensive study is needed, with promising impact upon the treatment and randomized controlled trials might measure the effectiveness of new tailored interventions, in order to alleviate the burden of endometriosis.

TISSUE PENETRABILITY OF NANOPARTICLES LOADED WITH RHODAMINE B FLUORESCENT MARKER USING A TRIMODAL ADMINISTRATION APPROACH (Abstract): Nanoparticles can incorporate a drug, as means of protection towards body physiological barriers, and release it in a controlled manner in a targeted tissue. This study aims to investigate the absorption of nanoparticles, loaded with Rhodamine B fluorescent marker, in different organs, by trimodal administration: endogastric, intraperitoneal and intravenous, for three days. **Materials and methods:** The extent of absorption of Rhodamine B dye in liver, gums, kidneys, ovaries and testes was determined using fluorescence microscopy in frozen sections on harvested organs from rats. The experiment required 24 adult male rats that were divided into four groups of six rats each. Group A was designated as the control group, while the other three groups, B, C and D, respectively, received Rhodamine-loaded nanoparticles for three consecutive days, at a dose of 0.05 mg/kg body weight. The methods of administration for the three study groups were as follows: endogastric for group B, intraperitoneal for group C, and injection into the tail vein for group D. On the fourth day the animals were sacrificed, and organs were removed and preserved in paraformaldehyde containers, to be studied under an immunofluorescence microscope. A four-level scale was used to evaluate organ penetrability for the given nanosystems. **Results*:*** Intraperitoneally administrated nanocarriers, marked with Rhodamine B, showed the highest degree of absorption in liver in 83.3% of the rats, compared to the endogastric route, where the same level of absorption was in only 33.3% of the animals (p=0.050). Regarding the two parenteral tested pathways, the absorption level presented statistical differences among the intraperitoneal vs. intravenous groups, in gum (p=0.011), heart (p=0.004), kidney (p=0.050) and testicle (p=0.011), whereas there was no statistical difference in liver tissue (p=0.250). **Conclusions:** The parenteral routes of administration had statistically significant higher organ penetrability, compared to the endogastric tube. Amongst the organs, liver had the most absorptive behavior due to its intrinsic metabolizing role, and there was no major difference between the intraperitoneal vs. intravenous injections. **Keywords:** RHODAMINE B, NANOPARTICLES, ENDOGASTRIC, PARENTERAL ABSORPTION.

Nanomedicine is the science of applying nanotechnology and nanosized materials in the medical field, in order to be used in the prevention and treatment of various pathologies (1). Based on the latest technological advances, nanotechnology became a frequently addressed topic in many research areas in the biological, and especially medical sciences. Within the pharmaceutical field, the primary advantages lie in the development of nanodrugs, as avant-garde medical therapies that open new horizons and challenges in targeting specific tissues (2-4).

This future drug administration was subject to skepticism at first, because nanoscale formulations have different physical and chemical properties compared to conventional drugs. In the case of noncarrier drugs, these properties are impacted by the physiological barriers of the organism, causing the destruction of the pharmacokinetic profile of drugs (2).

With the help of nanotechnology, three important directions have been approached in medicine: establishing or confirming a diagnosis following administration, control of the drug release proprieties, and influencing tissue regeneration capacity. Nanotoxicology is another field which started emerging, due to the exposure to airborne nanosized particles during manufacturing and manipulation processes (5). Nanomedicine has the ability to open new opportunities in terms of clinical applicability, by introducing new therapies for previously untreated pathologies. Drug nanosystems can integrate into their structure certain substances which, due to high toxicity, could not have been used on their own before. This decrease in toxicity, coupled with the power to control the delivery of the drug while overcoming biological barriers without degradation, prove their importance in current medicine. The therapeutic success is reflected in the in-depth research of the properties of nanodrugs to have the desired action, in the targeted tissue in the body (6, 7).

Rhodamine B as a synthetic dye has numerous uses, both in medicine, as a marker, as well as in the textile industry, food industry or cosmetology. The color obtained from the usage of Rhodamine B is green or red purple (8). This happens because exposing of the synthetic dye to light, leads to two types of reactions where reactive oxygen compounds are formed (9,10). There were some studies aiming to investigate the usage of Rhodamine B as a possible photochemotherapy for bladder cancer (11). However, the toxic profile for this compound has proved to be unsatisfactory since its administration through food in both human and animal studies can cause numerous digestive pathologies, following its accumulation in the digestive system (12).

In our study, Wistar white rats were chosen as a research tool, due to their immunological similarities with humans. Wildner demonstrated that the immunological link between rats and humans is due to major histocompatibility and the presence of activated Tregs cells (13).

The biocompatibility of nanomedicines is the starting point for treating several pathologies. Since they can overcome physiological obstacles specific to digestive tract, they offer the opportunity to reach the target organ without previously breaking down. Blais *et al*. reported the

high similarities between the metabolic pathways of humans and rats (14).

The aim of this study was to study the penetration of nanoparticles marked with Rhodamine B into several tissues using different routes of administration.

MATERIALS AND METHODS

Basic reagents

The chemicals used in this study were: Rhodamine (Octadecyl Rhodamine B Chloride (R18), Sigma), 1,2-Distearoyl-sn-glycero-3-phosphocholine (DSPC, Avanti), Cholesterol (CHOL, Sigma Aldrich), Methanol (Sigma Aldrich), Chloroform (Sigma Aldrich), Milli-Q ultrapure distilled water (Merck). The substances were used without additional purification, as they were purchased at analytical grade.

Rhodamine-marked liposomes preparation

In our study we obtained liposomes (LPs) of two types, small unilamellar vesicles (SUV) and multilamellar vesicles (MLV), using a slightly modified protocol based on the thin film hydration method used by Ciobanu *et al*. (15).

The early stage consisted of dissolving DSPC (120 mg) and CHOL (80 mg) in a Chloroform/Methanol mixture (4 mL / 4 mL) (1:1 v/v). Solvent extraction was performed by evaporation (using a rotary evaporator - Heidolph Laborota 4002 - at 60 rpm, 35°C and reduced pressure) from a round-bottomed flask (100 mL), thus obtaining a thin film on the wall of the flask. Following the extractive process, the obtained lipid film was hydrated with 10 mL rhodamine solution (RHD) at 25°C. The pre-hydration step is followed by the use of the vortex leading to the formation of MLVs. To eradicate the possibility of aggregate formation and in order to obtain a homogeneous suspension, the RHD-labeled MLVs suspension was placed in a sonicator bath for 10 minutes at 25°C. Water washing by centrifugation (12 revolutions at 15,000 rpm/15 min) was used for separation of the MLVs from unabsorbed RHD. Obtaining SUVs required a supplementary step, where MLV suspension was repeatedly extruded through decreasing size polycarbonate membrane (400 nm, 200 nm and 100 nm), using a miniextruder (Avanti Polar Lipids, Alabaster, AL). In the final stage, the obtained suspension of RHD-labeled SUVs was purified by dialysis against Milli-Q water with a cellulose ester membrane bag (molecular-weight cutoff = 12400) for 5 days.

MLVs and SUVs size determination

Laser diffractometry technique (SHIMADZU SALD 7001) was used to analyze MLVs and SUVs, the measurements being made in a triplicate manner to mitigate intrinsic preparation and assay errors. The steps are as follows: a) sonication of suspensions of MLVs and SUVs (50 μL) was performed for 10 minutes at room temperature, using the sonication bath (Bandelin Sonorex); b) the sonicated suspension was put into 10mL of double-distilled water; c) the resulted solution was added to a quartz vat equipped with a stirring mechanism and analyzed.

The analyzed SUVs and MLVs distribution curves (fig. 1 and fig. 2) have a unimodal appearance and a diameter in the submicron range (75-87 nm).

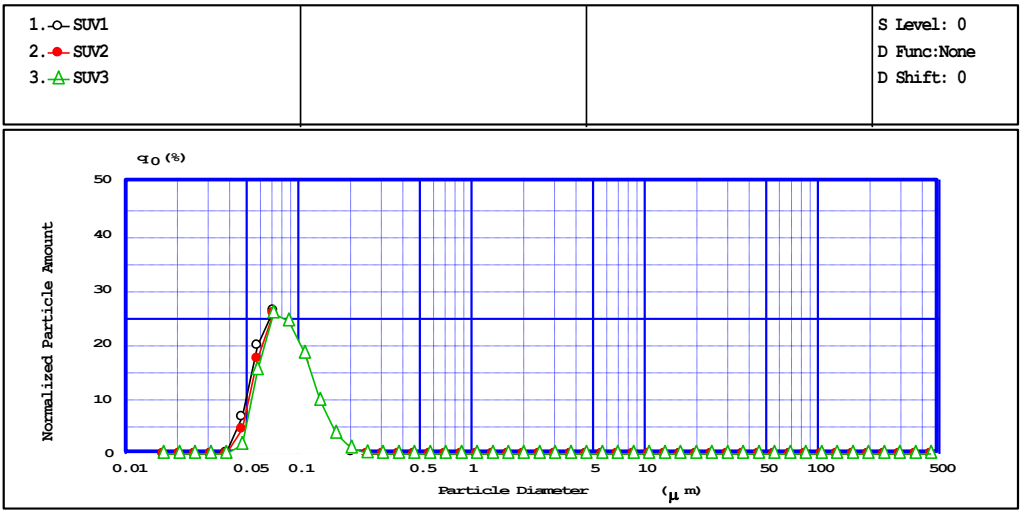

Fig. 1. Laser beam diffractometry for small unilamellar vesicles (SUVs). Distribution curves for particle diameter in the triplicate assay (SUV1=80nm; SUV2=83nm; SUV3=87nm).

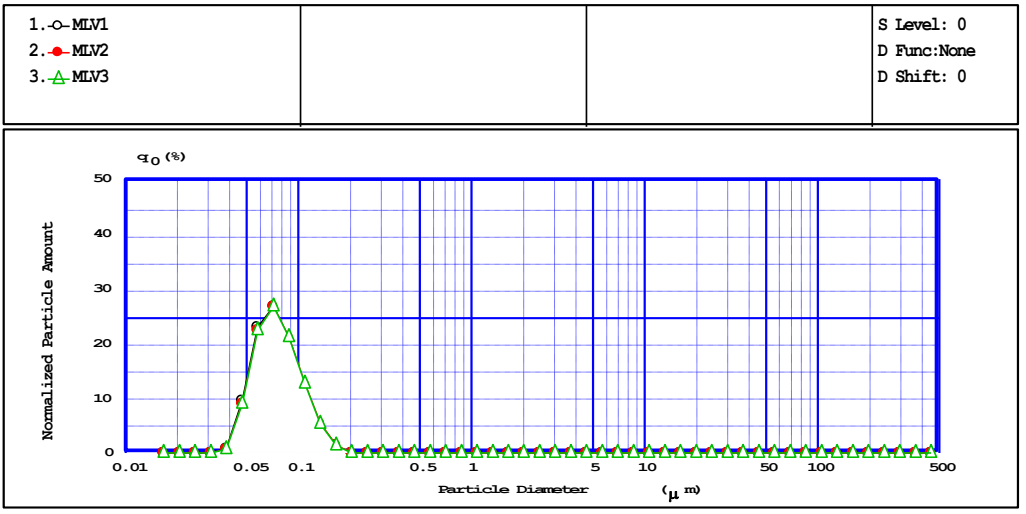

Fig. 2. Laser beam diffractometry for multilamellar vesicles (MLVs). Distribution curves for particle diameter in the triplicate assay (MLV1=75nm; MLV2=76nm; MLV3=76nm)

Phospholipid concentration assessment

The Stewart assay was used to quantify phospholipids (PLs) according to Torchilin (16). Initially we used a solution of Ammonium Ferrothiocyanate (0,1 M) and a specific calibration curve for the DSPC. Ammonium Ferrothiocyanate resulted by mixing Ferric Chloride hexahydrate (27.03 g) with Ammonium Thiocyanate (30.04 g) in double-distilled water, followed by subsequent dilution to 1000 mL.

The concentration of PLs was measured

by combining 0,5 mL suspension of SUVs (or MLVs, respectively) with 2 mL Chloroform and with 2 mL Ammonium Ferrothiocyanate solution (0,1 M) in 10 mL-tubes, protected on the exterior with aluminum foil. The previous step was done in a duplicate manner to cover for any accidental preparation errors. Each tube underwent rigorous vortexation for 30 seconds and then allowed to react 20 minutes in standard laboratory environment. After this time, the bottom layer was collected with a Pasteur pipette. The PLs-containing Chloroform phase was analyzed with a spectrophotometer at 485 nm. The concentration of PLs in the suspensions of SUVs and MLVs, respectively, was calculated by comparison of the PLs content with an anteriorly prepared standard calibration curve. PLs concentrations determined by the Stewart test were 14.5 mg/mL for the SUVs, respectively 13 mg/mL for the MLVs suspensions.

This method of calculation has the following two main advantages: a) the formation of a red color complex between the main groups of PLs with Ammonium Ferrothiocyanate, which can be quantified spectrophotometrically after extraction in an organic solution (Chloroform); b) there is no interaction between the assessment method and the inorganic phosphate.

Laboratory Animals

We used 24 white male Wistar rats, provided by the "Cantacuzino" National Medical Military Institute for Research and Development from Bucharest, Romania.

The animals were not genetically modified and presented a normal health status. Their age at the beginning of the study was 3 months, and their weight was varying between 200 and 250 grams. All animal subjects received daily appropriate nutrition and were accommodated in a controlled environment (temperature 25˚C, humidity 60%) at the Advanced Center for Research and Development in Experimental Medicine (CEMEX) of Grigore T. Popa University of Medicine and Pharmacy Iasi.

Certificate No. 93/14.06.2021 was issued by the Ethics Commission of "Grigore T. Popa" University of Medicine and Pharmacy, Iasi.

Main experiment steps

The subjects were divided into four groups, each consisting of six rats, and were given nanoparticles loaded with the fluorescent marker Rhodamine B. Each group had a different method of administration, except for Group A, designed as the control group who did not receive any substances. The other three groups, B, C and D respectively, were made of 6 rats, and received Rhodamine B loaded nanoparticles at a dose of 0.05 mg/kg body weight for three consecutive days. The methods of administration were as follows: endogastric for Group B, intraperitoneal injection for Group C and injection into the tail vein for Group D.

On the fourth day, the animals were sacrificed, and organs (gum, liver, heart, kidney, testicle) were harvested and preserved in paraformaldehyde to be examined under an immunofluorescence microscope (Nikon's Eclipse E600). Histological sections were performed with a LEICA CM1860 UV microtome at St. Mary Children's Emergency Hospital in Iasi, Romania. Fixation was done with glycerol mixed with resins, to prevent ice crystals formation when tissue was cryogenized at -40°C. After the tissue block opacified

entirely, we sectioned it in 5.0 μm slices, at -16°C. Sections were spread with an antiroll plate on glass slides and Meyer albumin was added to support the process. Fluorescence Mounting Medium (DAKO) was applied on these tissue fragments before the cover glasses were positioned (17).

Data analysis

The data were centralized in *SPSS 18.0* databases and processed with suitable statistical functions. Both descriptive and analytical methods were used.

Indicators of the average value were used in conjunction with the ones for dispersion. In calculating the significant difference between two groups with normal distributions, t-Student Test was done at a significance threshold of 95% ($p \leq 0.05$).

The plotting of a Receiver Operator Characteristic (ROC) curve, which defines the aria under curve (AUC) and where the false-positive rate (specificity) is placed on the abscissa and the true-positive rate (sensitivity) on the ordinate, allowed the analysis of the sensitivity/specificity balance.

The Kruskal-Wallis test is a nonparametric test with which we compared three or more frequency distributions intergroupally.

RESULTS

During microscopic examination, we observed several aspects regarding the absorption of Rhodamine B marked nanoparticles. Fluorescence is identified at the level of hepatic tissue, especially due to the Kupffer cells endocytosis (figs. 3a, 3b) and in the renal tubules, with a diffuse aspect (fig. 4).

At gingival level, the gum muscle fibers and the surface epithelium are visible displaying less fluorescence than the liver tissue (fig. 5). Seminiferous tubules incorporating the fluorescent marker were observed in the testicle (fig. 6).

Intraperitoneally administrated nanocarriers, marked with Rhodamine B, showed the highest degree of absorption in liver in 83.3% of the rats in Group C, compared to the endogastric route, where the same level of absorption was recorded in only 33.3% of the animals (p=0.050).

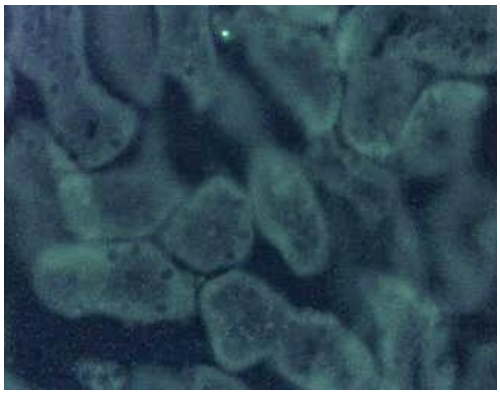

Fig. 4. Microscopic image of kidney tissue displaying diffuse fluorescence at the level of renal tubules, following administration of Rhodamine B nanoparticles by endogastric tube (x200)

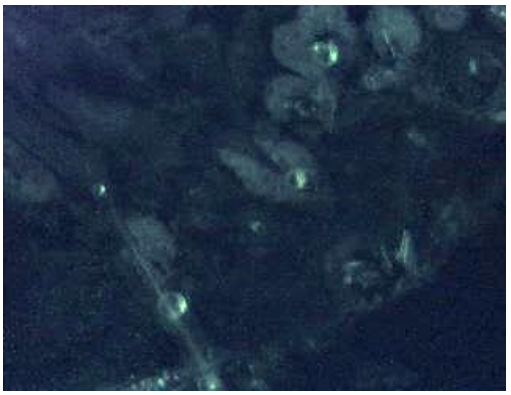

Fig. 5. Microscopic image of gingiva displaying fluorescence at the level of gingival muscle, following administration of Rhodamine B nanoparticles by intravenous injection (x200)

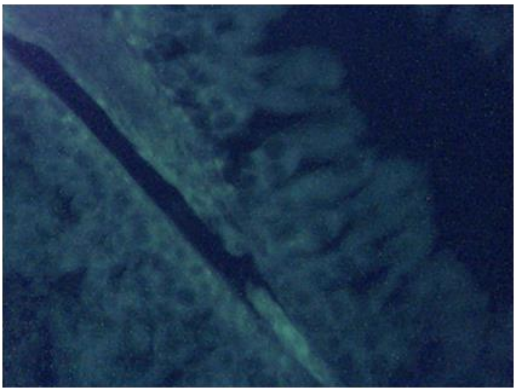

Fig. 6. Microscopic image of testicle tissue displaying fluorescence at the level of seminiferous tubules, following administration of Rhodamine B nanoparticles by intravenous injection (x200)

In what concerns the two parenteral tested pathways, the absorption level presented statistical differences among the intraperitoneal vs. intravenous groups, in gum ($p=0.011$), heart ($p=0.004$), kidney ($p=0.050$) and testicle ($p=0.011$), whereas there was no statistical difference in liver tissue ($p=0.250$). The penetrability of nanoparticles encapsulating Rhodamine B was quantified according to the observed fluorescence into four absorption levels: “very low absorption / no absorption” (-), “low absorption” (+), “moderate absorption” (++), “high absorption” (+++) (tab. I).

Kruskall-Wallis test delivers the correlation matrix between the degree of absorption of nanoparticles by type of organ, within each of the three groups. Significant differences ($p\leq0.05$) in the endogastric pathway are present between the absorption levels in the heart and kidney, heart and testicle, and kidney and testicle. In the intravenous group the only significant difference was observed between the liver and the testicle examined specimens. (tab. II).

TABLE I.

Fluorescence level following Rhodamine B marked nanoparticles absorption in the harvested organs in all study groups.

By drawing the ROC curves we highlighted the sensitivity and the specificity of the penetrability of Rhodamine B charged nanosystems into the examined organs, according to the route of administration (fig. 7, tab. III). In study animals receiving endogastric nanoparticles, the sensitivity/specificity balance of the degree of absorption in the liver was noted with a sensitivity of 79% and a specificity of 75% (AUC=0.792; IC95%:0.518-1.066; p=0.093), in kidneys with a sensitivity of 82% and specificity of 68% (AUC=0.722; IC95%:0.416-1.0029; p=0.200), and in the testicle with a sensitivity of 66% and specificity of 58% (AUC=0.667; IC95%: 0.331-1.002; p=0.337).

In study subjects who received Rhodamine-loaded nanoparticles by intraperitoneal injection, gum absorption degree displayed a sensitivity of 83% and specificity of 70% (AUC=0.833; IC95%:0.590-1.077; p=0.055).

In study subjects who received rhodamine-loaded nanoparticles through the tail vein, the degree of absorption in the heart was noted with a sensitivity of 75% and a specificity of 60% (AUC=0.736; IC95%:0.423-1.049; p=0.034), in the testicle with a sensitivity of 75% and specificity of 50% (AUC=0.722; IC95%:0.397-1.047; p=0.039), and in the gum with a sensitivity of 65% and a specificity of 80% (AUC=0.653; IC95%: 0.355-0.951; p=0.303).

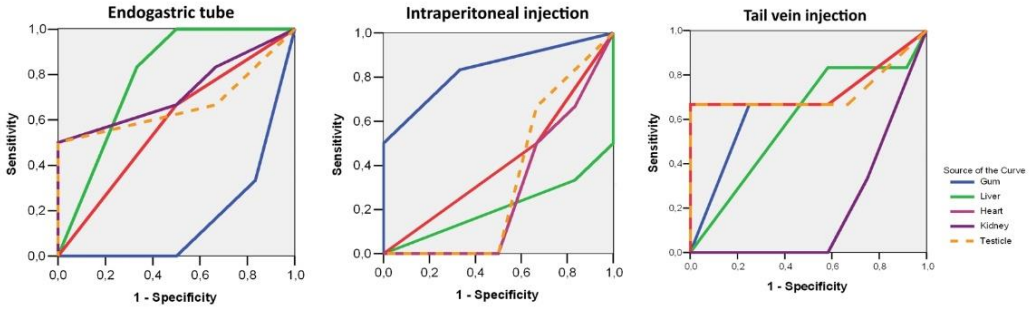

Fig. 7. Sensitivity and the specificity of the penetrability of Rhodamine B charged nanosystems into the examined organs, depending to the route of administration.

DISCUSSION

In recent times, there is growing evidence that nanosystems can be used as promising transporters towards tissues, and even certain cells from an area with specific pathology. Moreover, these carriers possess an adjustable drug release capacity, and also, they can avoid degradation due to digestion at gastrointestinal level.

Shah S *et al*. advocates for usage of correctly manufactured nanomedicines in the treatment of patients diagnosed with cardiovascular, neurodegenerative, and metabolic diseases, and in autoimmune pathologies or cancer. The numerous advantages, like avoiding first-pass metabolism or eliminating the gastrointestinal barrier in case of oral administration, coupled with efficient absorption and quick delivery in a targeted manner favors a wider-more spread implementation in the pharmaceutical industry (18). To reduce the toxicity of drug nanocarriers, their preparation uses biodegradable, biocompatible and physiological lipids (19).

The reasoning for the present paper was represented by a systematic approach to dye-marked nanoparticles absorption in several organs, by comparing three routes of administration: endogastric tube, intraperitoneal and intravenous injections. At present there is a scarcity of data in the literature regarding a comparison for absorption of these molecules in a trimodal administration.

The administration of nanoparticles can be achieved by enteral and parenteral pathways, with implications in patient quality of life. The oral route is the easiest and most common one, since has the highest patient addressability, but can be prone to variable intestinal absorption due to

digestion processes. The parenteral routes avoid intestinal barrier, but still organ absorption is correlated with blood flow distribution within the targeted tissue (20).

Intravenous injection enjoys a standard status in the hospital or out-patient clinic settings, having a rapid and entire dose delivery into the bloodstream (21). It is generally used in cases where nanosystems cannot be administered orally, patients are unconscious, or the nanodrug cannot be absorbed at the gastrointestinal level or where there are bleeding conditions in the digestive tract (22). Regarding the intraperitoneal route, it is common in the hospital practice only in limited areas like peritoneal dialysis and in the administration of radiopharmaceuticals, like 18F-fluorodeoxyglucose for the PET/CT studies (23).

The research in our preclinical study on the penetrability of Rhodamine B-loaded nanoparticles by parenteral administration and endogastric probe correlate with those conducted by Dias ML *et al*., who also investigated drug-carrying nanosystems in several delivery techniques. Dias ML has shown the effect on prostate cancer by using a chemotherapy drug (Paclitaxel) combined with a cholesterol-rich nanoemulsion given to mice. The action of this nano formula primarily targeted solid tumors and cancer cells, which increases the transcription frequency of low-density lipoprotein receptors. At the same time, the toxicity level of nanodrug structures was evaluated, together with an increase in the anticancer activity (24). Besides some major favoring elements, these carrier systems also come with some disadvantages, like a disparity between large-scale production and final selling price, presence of organic solvent residues in the final product, toxicity, and difficulty in granting licenses their usage from regulatory authorities (25).

In our study, the nanoparticles were loaded with the fluorescent marker Rhodamine B to study penetrability across several organs. Rhodamine is a synthetic dye with a stable chemical structure, easily assimilated by the body. It is widely used in immunofluorescence microscopy and flow cytometry (26), and also in biology and biotechnology as a biosensor (27, 28). Contrast dye has started being used in the last decade in formulations of nanomaterials for drug delivery with the purpose to evaluate absorption into tissues (29). Following exposure to light, Rhodamine can form reactive oxygen compounds in two ways: the first reaction is represented by the formation of reactive oxygen compounds by increasing the energy caused by Rhodamine and then transferred to biomolecules; the second reaction is characterized by the energy transfer of the immunofluorescent substance to the molecular oxygen (30).

Some studies suspect that this chemical compound is carcinogenic in rats and it can pose a genotoxic risk to mammals (31-34). However, there are currently no extensive studies proving that replacing the Rhodamine B dyes group with other fluorescent markers may mitigate these effects (35).

After administration of fluorescent marked nanoparticles, our study found that gum absorption was similar among the endogastric and intravenous administration pathways ($p=0.196$), but with a higher specificity, of 80% (AUC=0.653; IC95%:0.355-0.951; $p=0.303$), when injected into the tail vein. Gum tissue has dense vascularization, coupled with a high *in vivo* regeneration capacity (36), which is most probable to influence these findings.

Kupffer cells were highly captative of the fluorescent markers, since they are cells with important immune function due to their phagocytosis capacity, located in sinusoidal cells of the liver (37). The highest degree of absorption of nanocarriers was seen in the liver (+++) in 83,3% of the rats, in both cases of parenteral administration. We found

no statistical difference in the absorption at this level between the intraperitoneal and intravenous injections (p=0.250).

Leydig interstitial cells that secrete testosterone, along with Sertoli cells, which are support cells located in connective tissue (38), appeared fluorescent, but at a lesser extent in comparison with the liver tissue. We noted significant differences in the absorption among all three ways of administration at this level: intraperitoneal vs. endogastric (p=0.048), intravenous vs. endogastric (p=0.004), and intravenous vs. intraperitoneal (p=0.011).

Despite its toxicity evocated above (31-34), Rhodamine B itself is an optimal diagnostic method in various pathologies, being considered a fast, cheap and efficient marker (39). Incorporating Rhodamine B into nanoparticles could greatly diminish its toxicity, while still maintaining an adequate absorption profile in the target tissues. This was another reason for fulfilling the purpose of our study to make comparisons within the trimodal administration methods.

Very recent data is contradicting the genotoxicity of Rhodamine B in mammals, as it was successfully used as a biological marker, presenting low toxicity in the case of human embryonic kidney (HEK 293 cells). The absorption rate of the fluorescent marker was higher in cancer cells compared to normal cells, thus opening new opportunities in targeting tumors like skin neoplasms (B16F10 cells), breast cancer metastases (MDA-MB231 cells), lung carcinomas (A549 cells) (40).

This paper also opens up possibilities to continue the present research by implementing a more robust quantification system for the absorption of nanocarriers charged with Rhodamine B, with help of artificial intelligence processing for the fluorescence microscopy images.

Our study has involved a small number of laboratory animals, according to the Ethics Certificate issued by Grigore T. Popa University of Medicine and Pharmacy, Iași. This resulted in a limited power for our statistical analysis of the results.

CONCLUSIONS

Drug-carrying nanoparticulate systems are currently being used while also gaining increased attention, despite their high financial burden on the health systems.

Our study investigated the penetrability of nanoparticles loaded with Rhodamine B dye, following a trimodal administration method, for three consecutive days. The organ which showed the highest absorption, in both the tissular level and in the percentage of the studied subjects, was the liver, followed by kidney. The lowest absorption was seen in heart tissue.

After studying the penetrability of the fluorescent-marked nanoparticles, we have demonstrated that the studied organs had a high absorption rate, using the parenteral administration method, compared to endogastric probe.

LABORATORY ANIMALS RESEARCH ETHICS

Certificate No. 93/14.06.2021 was issued by the Ethics Commission of "Grigore T. Popa" University of Medicine and Pharmacy, Iasi.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest.

The present study received financial support from "Grigore T. Popa" University of Medicine and Pharmacy, Iasi, Romania, in the research program at the Doctoral School of the first author.

THE PROGNOSTIC VALUE OF CEA AND CA 19-9 IN DETERMINING SURVIVAL OUTCOMES FOR PATIENT WITH LOW RECTAL CANCER (Abstract): The prognostic value of carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9) is a topic of interest for surgeons. The aim of this retrospective study was to evaluate the prognostic value of CEA and CA 19-9 in patients with locally advanced low rectal cancer who underwent neoadjuvant chemoradiotherapy, underlining their potential as indicators for survival outcomes**. Materials and methods:** Between November 2019 and February 2023, we evaluated the medical records of 104 patients admitted to the first Oncologic Surgical Clinic from the Regional Institute of Oncology, Iasi, Romania. Clinical and paraclinical data was recorded, and patients were segregated intro three groups: one marker elevated during follow-up (group 1), 2 markers elevated during follow-up (group 2), and no marker elevated during follow-up (group 3). The overall survival and recurrence-free survival were the evaluated outcomes, and the prognostic values of serum markers were evaluated using Cox regression model and Kaplan-Meyer survival analysis. (3) **Results:** The presence of one (hazard ratio, HR: 2.78, 95% confidence interval, CI: 1.11- 6.92, p= 0.02) or both (HR: 4.23, 95%CI: 1.44-9.32, p=0.03) elevated markers statistically decreased the recurrence-free survival time. A combination of elevated markers has a significantly higher impact on the recurrence-free survival time compared to a single elevated marker (p=0.001). Only the combination of biomarkers significantly decreased the overall survival rates (HR: 3.74, 95% CI: 0.57- 7.62, p= 0.04). (4) **Conclusions:** The combination of elevated CEA and CA 19-9 had the highest prognostic significance for the evaluated survival outcomes. **Keywords:** LOW RECTAL CANCER; CEA; CA 19-9; SURVIVAL OUTCOMES.

Low rectal cancer presents unique challenges and considerations compared to other colorectal malignancies, particularly concerning therapeutic strategies and prognostic evaluations (1). Approximately 46,000 new cases of rectal cancer are identified annually in the United States (2). The majority of them are adenocarcinomas (3).

Comparable epidemiological data was obtained from Europe, and current GLOBOCAN statistics for 2022 revealed that colon cancer ranked as the third most commonly diagnosed form of cancer in males, with 92,942 newly diagnosed cases in Eastern Europe (4). According to the data registry, colorectal cancer was identified as the second most commonly diagnosed tumor in Eastern Europe's female population, with a total of 86,575 new cases reported in 2022. In Romania, there was a close adherence to the epidemiological trend of colorectal cancer. In 2022, there were 8,056 newly diagnosed cases in males, making it the third most common kind of cancer. In females, there were 5,485 newly diagnosed cases, making it the second most common type of cancer (4).

The survival rates for rectal cancer have significantly increased in the past 30 years due to various factors, one of which is the implementation of neoadjuvant radio chemotherapy (RCT) (5). This treatment is now recommended for almost all cases of locally advanced rectal cancer (LARC) that are classified as cT3 and T4. It is evident that patients who respond well to RCT have a higher chance of achieving a better prognosis. These good responders make up approximately 15-27% of all patients treated with RCT (6).

The gold standard for evaluating the response of primary tumors after RCT is histopathological analysis of the surgical specimen. This analysis includes determining the pathological tumor regression grade (pTRG) by assessing the proportion of residual tumor cells and fibrosis within the tumor specimen (7).

Magnetic resonance imaging (MRI) is widely recognized as the most precise method for determining tumor stage, involvement of the mesorectal fascia, and invasion of blood vessels outside the wall of the rectum (8-10).

Recent investigations have shown an association between MR imaging results and pathological TRG (pTRG) (11, 12). Also, several studies suggested a scoring method called MR imaging-TRG (mrTRG), which is determined through visual evaluation of MR imaging data (13, 14).

The determination of survival outcomes is a multifaceted process, influenced by a diverse array of clinical, pathological, and molecular factors (15-17). Among these, tumor markers play a critical role in informing prognosis and guiding therapeutic decisions. Carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9) are two such biomarkers which have been widely studied for their prognostic implications in colorectal cancer (18, 19). Their levels are often correlated with disease stage, tumor load, and patient outcomes, and they may be particularly significant in the context of low rectal cancer (20, 21).

CEA is the most prominent biomarker for colorectal cancer, and it is used preoperative staging, therapy monitoring, and postoperative follow-up [10, 11], while CA19-9 is closely associated with the biological characteristics of tumors. The rectum and colon exhibit distinct variations in embryology, architecture, and physiology.

Furthermore, there are apparent differences in the development of rectal and colon cancer. Therefore, additional research is required to investigate the significance of CA19-9 in rectal cancer, particularly in patients with locally advanced rectal cancer who are having neoadjuvant

chemoradiotherapy.

This paper examines the prognostic value of CEA and CA 19-9 in patients with locally advanced low rectal cancer who underwent neoadjuvant chemoradiotherapy, underlining their potential as indicators for survival outcomes. The pursuit is to deepen the understanding of these biomarkers beyond the usual confines of diagnostic tools, exploring how their preoperative and post-operative levels relate intricately to clinical trajectories and long-term survival rates.

MATERIALS AND METHODS

We performed a retrospective observational study at in the first Oncologic Surgical Clinic from the Regional Institute of Oncology, Iasi, Romania, between November 2019 and February 2023. Ethical approval for this study was obtained from the Institutional Ethics Committees of the "Grigore T. Popa" University of Medicine and Pharmacy Iasi (No. 23103/23rd of October 2019) and of the Regional Institute of Oncology (No. 245/3rd of July 2019).

In this study we included patients diagnosed with low rectal tumors (less than 8 cm from the anal verge), a histopathological examination that indicated adenocarcinoma type, who had a preoperative pelvic MRI for staging, and who received neoadjuvant therapy, as well as those who offered their informed consent for participating in this study.

The exclusion criteria comprised patients with rectal cancers who needed emergency surgery, other subtypes of rectal cancer, loss of follow-up, incomplete medical data or lack of informed consent.

The following data was recorded: demographic and clinical characteristics, the levels of CEA and CA 19-9 before surgery and during follow-up, preoperative MRI parameters, histopathological examination of pre-operative biopsies and post-operative specimens, type of surgery, postsurgical evolution and survival (overall survival and recurrence-free survival). All patients underwent pelvic MRI examination the SIEMENS MAGNETOM Avanto I-class 1.5 Tesla machine (Siemens Healthcare GmbH, Erlangen, Germany).

The examination protocol included the visualization of the pelvis in all three planes:

- Sagittal – this plane was used to locate the tumor and to plan the axial and coronal sequences;
- Axial - the plane was angled perpendicular to the tumor to correctly visualize the extension of the tumor against the rectal wall, as well as the distance between the tumor and the mesorectal fascia (MRF);
- Coronal – the plane was angled parallel to the axis of the tumor, which is perpendicular to the axial series.

The sequences used are the following: multiplanar T2w and T1w that provided valuable morphological information due to the high resolution of anatomical structures. The T2w sequence was $\leq$ 3 mm thick. The preoperative parameters included: distance from anal verge, extramural venous invasion (EMVI) status, and MRI CRM (mCRM) positivity.

CA 19-9 was determined from the serum of the patients (at least 0.5 mL) using immunochemistry with electrochemiluminescence detection (ECLIA) (Roche Diagnostics GmbH, Mannheim, Germany). A cut-off value was considered <27 U/mL[3] for this biomarker. Another 0.5 mL of blood serum was used to detect CEA using the same ECLIA protocol, and the cut-offs

of this marker were considered as follows: <3.0 ng/mL (non-smokers), and <5.0 ng/mL (smokers).

The values of these biomarkers were recorded before surgery, and any increase of the serum values during follow-up were recorded. If none of these markers were increased during follow-up, the patients were included in the control group (group 3, n= 68 patients). If one of these markers were positive, the patients were included in the first group (n= 24 patients). Finally, if both of these markers were positive during monitorization after surgery, the patients were included in the second group (n= 12 patients). Our data is limited to three years after surgery, and the follow-up consisted of consultation at 3-monthly intervals for the first 2 years, and every 6 months for the third year.

Each patient underwent an extended course of radiation, receiving a total dose of 45 Gy administered in 25 fractions. This was followed with a supplementary dose of 5.4 Gy specifically targeting the primary tumor, administered over a period of 5 weeks. The preoperative concurrent chemotherapy regimens consisted of either capecitabine plus oxaliplatin (CapeOX) or fluorouracil plus oxaliplatin (FOLFOX). The surgical procedures were conducted 6-8 weeks following the preoperative neoadjuvant chemoradiotherapy.

Considering the overall survival and recurrence free survival as outcomes, we compared categorical and continuous data between groups using Pearson's $\chi 2$ test or analysis of variance (ANOVA), followed-up by Bonferroni post-hoc test. We have also used a Cox regression model with Breslow method for ties to identify the impact of the evaluated biomarkers for the prediction of overall survival and recurrence-free survival, and quantified their impact as hazard ratio (HR) and 95% confidence interval (CI).

Finally, we provided a survival analysis of our cohort of patients using Kaplan-Meier estimates, segregated depending on the presence of one or two elevated biomarkers during follow-up. A p-value less than 0.05 was considered statistically significant. These analyses were performed using STATA SE (version 17, 2023, StataCorp LLC, College Station, TX, USA).

RESULTS

This study evaluated the medical files of 104 patients with low rectal adenocarcinoma who received neoadjuvant CRT and surgical treatment. Their demographic and clinical characteristics are presented in table I. We could not find any statistically significant difference between groups regarding their baseline characteristics such as age (p= 0.72), gender distribution (p= 0.67), or body mass index (BMI) (p= 0.98).

On the other hand, patients who had one or both biomarkers increased during follow-up presented with significantly higher frequency of positive mCRM, EMVI, anterior location of the tumor, a distance from the anal verge less than 4 cm, incomplete TME, and positive pCRM (p< 0.001).

The impact of elevated serum markers on the recurrence-free survival and overall survival was tested using a Cox regression model with Breslow method for ties (table II). Our results indicated that the presence of one (HR: 2.78, 95% CI: 1.11- 6.92, p= 0.02) or both (HR: 4.23, 95%CI: 1.44-9.32, p= 0.03) elevated markers statistically decreased the recurrence-free survival time.

Also, a combination of elevated markers has a significantly higher impact on the recurrence-free survival time compared to a single elevated marker (p= 0.001).

On the other hand, only the combination of biomarkers significantly decreased the overall survival rates (HR: 3.74, 95%CI: 0.57- 7.62, p= 0.04), and the comparison between groups was statistically significant (p= 0.042).

TABLE I.

Demographic and clinical characteristics of patients included in the study

Variable	One elevated marker (group 1, n= 24 patients)	Two elevated markers (group 2, n= 12 patients)	Control group (group 3, n= 68 patients)	*p* value
Age, years (mean ± SD)	64.72± 7.41	69.16± 6.32	64.87± 7.93	0.72
Gender (n/%)	Male= 15 (62.50%) Female= 9 (37.50%)	Male= 9 (75%) Female= 3 (25%)	Male= 42 (61.76%) Female= 26 (38.24%)	0.67
BMI, kg/m^2 (mean ± SD)	25.15± 4.29	25.18± 3.88	24.86± 4.10	0.98
Positive mCRM (n/%)	Yes= 19 (79.17%)	Yes= 5 (41.67%)	Yes= 0 (0%)	< 0.001
Positive EMVI (n/%)	Yes= 14 (58.33%)	Yes= 9 (75%)	Yes= 2 (2.94%)	< 0.001
Anterior location (n/%)	Yes= 9 (37.50%)	Yes= 6 (50%)	Yes= 1 (1.47%)	< 0.001
Distance from anal verge (n/%)	< 4 cm= 19 (79.17%)	< 4 cm= 10 (83.33%)	< 4 cm= 16 (23.53%)	< 0.001
Type of surgery (n/%)	AP resection= 15 (62.50%) Hartmann procedure= 6 (25.00%) Anterior resection= 1 (4.17%) Pelvic exenteration= 2 (8.33%)	AP resection= 8 (66.67%) Hartmann procedure= 2 (16.67%) Anterior resection= 2 (16.67%) Pelvic exenteration= 0 (0%)	AP resection= 53 (77.94%) Hartmann procedure= 11 (16.18%) Anterior resection= 4 (5.88%) Pelvic exenteration= 0 (0%)	0.11
Incomplete TME (n/%)	Yes= 12 (50%)	Yes= 5 (41.66%)	Yes= 5 (7.35%)	< 0.001
Positive pCRM (n/%)	Yes= 15 (62.50%)	Yes= 4 (33.33%)	Yes= 0 (0%)	< 0.001

pCRM - pathological (positive) circumferential resection margin; mCRM - positive circumferential resection margin on MRI; mrEMVI - extramural venous invasion on MRI; SD- standard deviation; BMI - body mass index; AP - abdominoperineal resection; TME - total mesorectal excision.

TABLE II.

Group comparisons of first trimester biochemical markers and mean arterial pressure

Marker	One elevated marker (group 1, n= 24 patients)	*p* value	Two elevated markers (group 2, n= 12 patients)	*p* value	*p* value* comparison
Recurrence-free survival (HR, 95% CI)	2.78 (1.11- 6.92)	0.02	4.23 (1.44- 9.32)	0.03	0.001
Overall survival (HR, 95%CI)	2.56 (0.78- 8.40)	0.12	3.74 (0.57- 7.62)	0.04	0.042

HR- hazard ratio, CI- confidence interval, *- *p* value resulted from comparison.

In the final stage of our analysis, we outlined the impact of these elevated markers on the survival estimates using Kaplan-Meyer analysis (figures 1 and 2). The recurrence-free survival estimates for the first group were 70.83% (n= 17 patients), with a medial time until the recurrence occurred of 29 months, while the recurrence-free survival estimates for the second group were 66.6% (n= 8 patients), with a median time until recurrence of 18 months.

The overall survival Kaplan-Meyer estimates for the first group were 83.7% (n= 20 patients), with a median time until the failure event (death) of 30 months, while for the second group the overall survival rate was 75% (n= 9 patients), with a median time until death of 32 months.

DISCUSSION

This observational retrospective study evaluated the prognostic value of CEA and CA 19-9 in patients with locally advanced low rectal cancer who underwent neoadjuvant chemoradiotherapy, underlining their potential as indicators for survival outcomes. Our results indicated that that the presence of one or both elevated markers statistically decreased the recurrence-free survival time. Also, a combination of elevated markers has a significantly higher impact on the recurrence-free survival time compared to a single elevated marker. On the other hand, only the combination of biomarkers significantly decreased the overall survival rates, and the comparison between groups was statistically significant.

These results are in line with previously published data. One recent study by Zheng *et al.* investigated the prognostic significance of CEA and CA 19-9 and their combination for patients with locally advanced rectal cancer (19). Their results indicated that the recurrence-free survival rates and the overall survival rated RFS and OS rates decreased as the serum levels of these markers increased during follow-up (all $p < 0.05$). The same study outlined that only the number of elevated post-neoadjuvant therapy markers was an independent prognostic factor the evaluated outcomes, and that a combination of serum markers increased the risk of recurrence and death (2.5- and 3.7-fold increased risk).

Another study included 197 cases with LARC who underwent neoadjuvant CRT and radical surgery, and the authors evaluated the prognostic significance of CEA and CA 19-9 for the following outcomes: survival rates as well as distant metastasis and local recurrence rates (22). The results from this study demonstrated that the combination of these markers achieved the best performance in terms of prognosis of disease-free survival (HR: 8.157, 95%CI: 3.232-20.591)

and distant metastasis (HR: 8.790, 95% CI: 3.324-23.248). They also found out that elevated CA19-9 was associated with poorer overall survival rates, disease-free survival rates, and local recurrence rates.

Song *et al.* investigated the prognostic significance of CEA serum levels firstly determined in six months after surgery in 100 patients with locally advanced rectal cancer treated with neoadjuvant CRT and total mesorectal excision (23). Their results indicated a median CEA value after surgery of 1.3 ng/mL, with an overall descending trend of serum values from before neoadjuvant CRT. Moreover, their multivariate analysis indicated that both a complete pathological response and an elevated postoperative CEA were significantly associated with local recurrence.

Finally, Kim *et al.* outlined the prognostic value of postoperative CEA levels over the overall survival rates and disease-free survival rates during a 5-year follow-up in a cohort of 122 patients with rectal cancer (24). Specifically, the overall survival rates were 62.3%, while the disease-free recurrence rates were 58.6% in patients with progressive decrease of CEA levels after surgery, and these rates were overall higher than those of patients with increased CEA levels after surgery. In our study, the overall survival rates and recurrence-free survival rates were higher, but the follow-up period was only of 3 years. Moreover, since the median reference time for the death occurrence in our cohort of patients was 30 and 32 months in the evaluated groups, we expect a possible decrease in the overall survival rates when evaluating data in a 5-year time-frame.

As low rectal cancer often necessitates a tailored therapeutic approach due to its anatomical and oncological characteristics, the evaluation of CEA and CA 19-9 may offer valuable insights into the aggressiveness of the disease, the likelihood of recurrence, and the chances of a favorable response to treatment. In the quest for precision medicine, dissecting the utility of these biomarkers is imperative to optimize patient management and improve prognostic accuracy, ultimately enhancing survival outcomes.

The results from this study should be interpreted considering the following limitations: the small cohort of patients, the limited time-frame for patients' follow-up. On the other hand, this study has the advantage of a homogenous cohort of patients considering the rectal tumor type and demographic data.

Artificial intelligence and risk stratification have been gaining more interest in the field of predictive medicine, and it has been frequently used in imaging data modeling in the recent years (25-31). We hypothesize that further studies, on larger cohort of patients, could include individual or combined serum markers in several machine learning or convolutional neural networks in order to better establish their prognostic value.

CONCLUSIONS

The follow-up of rectal patients who underwent neoadjuvant CRT and surgical therapy should include, among other investigation, the dynamic determination of serum values of CEA and CA 19-9.

In our study, the presence of one or both elevated markers statistically decreased the recurrence-free survival time. Also, a combination of elevated markers has a significantly higher impact on the recurrence-free survival time compared to a single elevated marker. Only the combina-

tion of biomarkers significantly decreased the overall survival rates.

Further studies should include the long-term follow-up of patients, and should incorporate more advance data modeling techniques for further prognostic stratification of these serum markers.

ATHEROGENIC INDEX OF PLASMA (AIP): CAN BE A BIOMARKER FOR EARLY ENDOTHELIAL DYSFUNCTION AND CARDIOVASCULAR DISEASE IN EXPERIMENTAL MODELS OF OBESITY RATS? (Abstract) **Objective:** Our experimental study evaluated the influence and correlation among the Atherogenic index of plasma and early histological endothelial dysfunction in an experimental model of obesity rats. **Materials and methods:** Twenty-one Wistar rats, male, aged 4–6 months (450-550g), were allocated into III groups. The control group consumed exclusively a standard food, while the II group was administered HFD (Hight-Fat-Diet) with 2% cholesterol and the last group received HFD and treatment with Atorvastatin 20mg/kg/day by gavages. Before and after 4 weeks of oral administration of diet and treatment, serum lipid profile and glycemia were measured. The Atherogenic Index of Plasma, Castelli risk indices (I and II) and lipoprotein combined indices (LCI) are evaluated with a formula. Also, for histological study, aortas were extracted for the histological investigation and the principal extracellular matrix components, including collagen and elastin, were examined with a microscope for indications of aortic degeneration. Endothelial dysfunction was evaluated with biochemical levels of lipid profile, abdominal ultrasonography and histological study. **Results:** Four-week diet supplementation with HFD for obesity rats caused an increase in serum lipids levels; AIP levels indicate a high risk for cardiovascular events, histological aspect we observed endothelial damage, with degenerative modification in the aortic media, indicating by the dissociation of elastic fibers and accumulation of collagen. **Conclusions:** In our study, AIP, lipoprotein combined index and Castelli's risk index I and II are correlated with endothelial injury. Obesity disturbs the lipid profile, increasing AIP in experimental models of obesity rats and can be a risk factor for endothelial dysfunction. Treatment with statin, healthy food and change in the

modifiable risk factors can improve endothelial function and early stage of atherosclerosis.

INTRODUCTION

Cardiovascular diseases (CVD) are considered the primary cause of death in the population, affecting women and men. The World Health Organization (WHO) predicted that in 2023, 23.3 million people will die caused by cardiovascular disease (1). Also, diabetes mellitus, obesity and metabolic syndrome continue to be the main factors that limit life (2) and are a major cause of reduced quality of life and disability.

The normal equilibrium of the vascular endothelium is considered the fundamental part of vascular health. The vascular endothelium has been considered, for a long time, only a simple cellular barrier, new is defined as an active monolayer that covers the cells of the vascular lumen, thus separating the vascular wall from the circulating blood. Over the years, authors have offered multiple definitions of endothelial dysfunction – ED (3). Endothelial dysfunction is definitely like the imbalance between vasodilation and vasoconstriction with excessive reactive oxygen species (ROS) and proinflammatory agents and decreased nitric oxide (NO) bioavailability (4).

Atherosclerosis, dyslipidemia and oxidative stress (OS), at present, are considered risk factors associated with CV and are responsible for millions of deaths annually (5). A major cause of premature mortality among CVD is atherosclerosis. It is considered a chronic, systemic, complex disease, who is affecting the vascular endothelium, characterized by lipid deposition in the arterial wall. Recent scientific research supports that atherosclerosis can be slowed or stopped, by initiating specific therapeutic measures and lifestyle modification and developing new therapeutic strategies capable of improving endothelial function and cardiovascular prognosis. The pathophysiology of atherosclerosis involves inflammation, abnormalities in lipoprotein metabolism and oxidative stress, which result in the accumulation of cholesterol esters in the macrophages of the arterial wall (6).

The primary contributing cause of coronary artery disease and endothelial dysfunction is dyslipidemia. Also, dyslipidemia plays a significant role in the carcinogenesis of various tumor types (renal, prostate and ovarian cancer (7). Atherogenic dyslipidemia is characterized by an abnormal lipid profile, a low level of high-density lipoprotein cholesterol (HDL-C)and increased levels of total cholesterol (TC), also, low-density lipoprotein cholesterol (LDL-C), apolipoprotein B and triglyceride (TG). Atherogenic dyslipidemia is the same, implicated in the pathogenesis of endothelial dysfunction, also, microvascular coronary pathology and atherosclerosis - contribute to the progression of atherosclerotic plaques (8, 9). Oxidized LDL (ox-LDL) contributes to atherosclerotic plaque development because it inhibits endothelium-dependent vasodilation by decreasing the activity of nitric oxide synthesis (10). The principal role of HDL is to protect

endothelial cells from the damaging consequences of LDL and increase their function (11). Recent studies have shown that hypertriglyceridemia inhibits endothelial function in a variety of ways (12). TG also promotes atherosclerosis by producing proinflammatory cytokines, fibrinogen and coagulation factors (13).

Furthermore, early diagnosis of endothelial dysfunction has an essential role in the prevention and detection of CVD; this could be a reversible first step in atherosclerosis. Endothelium dysfunction causes very small TG-high lipoproteins and residue molecules, recognized like ApoB which contain lipoproteins, to traverse the endothelium cell barrier, accumulating fat and atherosclerosis.

In 2001, Dobiášová and Frohlich discussed for the first time the Atherogenic Index Of Plasma (AIP) which represents the interaction between protective lipoprotein and atherogenic biochemical markers(14).A relatively recent marker of atherogenicity is the atherogenic index of plasma (AIP) and is evaluated with the classical formula *as log10 (TG/HDL-C).*It is considered a good biochemical predictor for cardiovascular pathology, which includes coronary artery physiopathology and a significant biomarker to estimate the risk of atherosclerosis.

According to previous studies, AIP was stratified into three groups: low (< 0.11), intermediate (0.11–0.21) and high-risk (> 0.21) (15). The AIP is considered a new complex lipid index that measures the equilibrium between the atherogenic and antiatherogenic components and has also been the subject of research in recent years.

Previous research has proved that the atherogenic coefficient, calculated as Non-HDL-C/HDL-C, Castelli risk indices I represent the report between [TC]/HDL-C and Castelli risk II - LDL-C/HDL-C had better predictability for CVD events and significant correlations with cardiovascular disease than simple lipid parameters.

The comprehensive lipid indexes, compared with single lipid parameters, such as non-HDL-C (TC minus HDL-C), TC/HDL-C, LDL-C/HDL-C, non-HLD-C/HDL-C (atherogenic index, AI), and TC*TG*LDL/HDL-C (lipoprotein combine index, LCI), are considered to be better predictors for cardiovascular diseases (16).

MATERIALS AND METHODS

Twenty-one Wistar male rats, 4-6 months (450-550g), come from the "Cantacuzino" Institute, Bucharest, Romania and then accommodated within the CEMEX animal research "Grigore T. Popa University of Medicine and Pharmacy", Iasi, Romania was included in an experimental study. The animals were placed in individually ventilated cages, with a specially designed room that had a temperature of 20 ± 4 °C, standard humidity (50 ± 5%) with 12 hours of cycle light/dark. They also had unlimited access to food and drink.

The experimental investigation was conducted according to the European Directive 2010/63/EU, with approval from the "Grigore T. Popa" University of Medicine and Pharmacy Iasi Ethics Committee (no. 277) and authorization from the Romanian National Sanitary Veterinary and Food Safety Authority (no. 61).

The present study was performed on three groups of 7 Wistar male rats, aged4-6 months, weighing 150 - 200 g for group control and weighing 450 - 550 g for a group with obesity. After 2 weeks of ac-

climatization, all the rats received food and treatment according to the experimental protocols.

The animals from the I group (control) have standard food and drink water ad libitum. The second and the III groups were Hight-Fat-Diet (HFD) with a 2% cholesterol-containing diet for 20 days and experimental groups (group III) were separately treated with Atorvastatin 20 mg/kg/day, every day, for the next 20 days, with gavages and water ad libitum. A recent study reported that using a dose of 20 mg/kg/day for the next Twenty days has not described any toxicity in rats and this can be a safe dose (17). Before being administered orally, Atorvastatin (Sortis, Pfizer, no NM4027) was taken in distilled water and administered once a day by gavages, using a sterile disposable for every animal feeding needle (20G × 1.1/2, Popper and Sons). Water was given to the control group via the same method as the treated groups. Every day, the quantity of water and food received was measured. Also, and on the same day, every week, body weight was measured.

Before and after 4 weeks of oral administration of Atorvastatin levels of lipid parametric (Triglyceride, Total Cholesterol, HDl-cholesterol, LDl-cholesterol) and Glycemia were analyzed. The AIP, atherogenic coefficient (AI), Lipoprotein combined index (LCI), and Castelli risk indices I and II are evaluated with the formula (results are notated in tables I and II).

Also, all the subjects were anesthetized and investigated with EKG performed in 6 leads, and abdominal ultrasonography. After 4 weeks, for histological study, the aortas were removed. The major extracellular matrix components, including collagen and elastin, have been evaluated microscopically as indicators of aortic modification.

Endothelial dysfunction has been evaluated with biochemical markers, abdominal ultrasonography and histological study.

Experimental procedures. Physiological and Biochemical markers. On the 20th day after oral administration of treatment, euthanasia was conducted on all subjects, followed by an intracardiac puncture to obtain 3-4 mL of terminal blood samples, which were then collected in 3 mL special vacutainer tubes with clot activator for biochemical assays. Following a half-hour harvesting period, the tubes were centrifuged for 15minutes at 1500x g, a temperature of 4°C. We separated serum samples for the subjects for biochemistry analysis. Following the manufacturer's explicit instructions, all reagents for the determination of biochemistry were obtained from *BioSystems S.A. (Barcelona, Spain)* and utilized with the automatic analyzer system *ACCENT-200 (PZ Cormay, Poland).*

Paraclinical Evaluation: Abdominal ultrasonography and Histopathology. The ultrasound was performed with the Vevo 2100, Visual Sonics, with a linear probe (MS 250S, 13-24 MHz). Subjects were abdominal trimmed and maintained in a supine position under inhalation anesthesia. The abdominal aorta was assessed in the longitudinal section. In B-mode the aortic wall, the aortic caliber at the mid-abdominal level and in pulsed Doppler mode the aortic flow velocity was measured.

Histopathology. Each animal had a thorough postmortem examination, which

included a rigorous examination of the bodies. During this examination, the abdominal aorta was removed and preserved in 10% formalin and let for up to 48 h for fixation, in full accordance with the updated guides for rats and mouse organ sampling and trimming for a more extensive histological study. After that, two sections of the abdominal aorta were placed on a microscope slide and stained according to the usual staining methodology for hematoxylin and eosin (H&E).

Statistical analysis. Through a comparative study between every group, all measurable parameters were evaluated. The data analysis process was carried out using *SPSS version 23.0* for Windows (SPSS, USA). Two-sided testing was used to evaluate with a statistically significant value of $p < 0.05$.

RESULTS

At the finally of the experiment study, all the animals were examined carefully. During surgery, we observed abdominal fat accumulation in group II and group III, even retroperitoneal fat was not evaluated for the classification of obesity. However, at the macroscopic evaluation, we don't observe aortic atherosclerosis in the control or obesity groups. In figure 2 shows the changes in body weights in all groups. In the tables I, II and III will see the biochemical changes in lipid profile, before and after treatment/experiment.

*OB- obesity, AT- Atorvastatin; I- Initial, Finally, **Statistically significant with $p < 0.05$;
***Statistically significant with $p < 0.001$ (paired t-test between before and after treatment values).

In the first group control, we see that there are no changes in biochemical values.

In group II- with obesity and HFD (cholesterol 2%), Total cholesterol levels increased, from an average of 178.43±12.23 mg/dL to 230.57±18.19 mg/dL, significantly ($p < 0.05$) and correlated with food received. LDL-cholesterol levels increased from 51.71±3.96 mg/dL to 53.71±2.42 mg/dL, but not statistically significant. Also, triglyceride levels increased from 168.29±9.2 to 182.86±3.31 but not statistically significant. Blood glucose levels increased, but not statistically significant during monitoring, from an average of 91.29±5.19 mg/dL to 101.0±2.57 mg/dL. In group III- with obesity and HFD (cholesterol 2%) and received Atorvastatin 20mg/kg/day, for the 20 days, it can be noted that the level of total cholesterol decreased from 270.0±23.71mg/dL to 169.86±3.36 and LDLc the same, from 49.71±1.64 mg/dL to 39.14±2.82 mg/dL (statistically significant with $p < 0.05$). The level of Glycemia and HDL_C increased but was not statistically significant. The experiment revealed that in group III, initial blood glucose values were above 119.0±19.34 mg/dL (the value considered physiological). We believe that these increased values were primarily due to stress caused by restraint, medication administration and explorations. The mean blood glucose value at the study's end was 131.29±19.95 mg/dL.

In all groups, we calculated the Atherogenic Index of Plasma- AIP with standard formula as TG/HDL_C and Atherogenic index – AI ($non\text{-}HLD_C/HDL_C$) (tab. II). In control groups, AIP increased but was not statistically modified. For group II, the obesity group with HFD (with 2% cholesterol) AI and AIP index levels increased, from an average of 2.60±0.23mg/dL to 3.42±0.46 mg/dL, also, 3.41 ± 0.18 to 3.49 ± 0.18, but not significantly and correlated with food received, age and weight and no treatment administrated. In group III**,** which received treatment with statin, we observed significantly lower levels of TC, LDLc, and TG (tab. I). Also, AIP and AI decreased statistically significantly with $p < 0.05$ in the final experiment, from levels 3.83 ± 0.29 to 2.48 ± 0.29*** and 4.04±0.73 to 2.21±0.12**** for the AI index (tab. II).

TABLE II.

Comparison of each study group before(initial) and after treatment for AIP and AI index. Values as Mean ± Standard error.

Parameter / Study group	(TG/HDL_C) ATHEROGENIC INDEX OF PLASMA (AIP)		$Non\text{-}HDL_C/HDL_C$ ATHEROGENIC INDEX (AI)	
	I (mean ± SE)	F (mean ± SE)	I (mean ± SE)	F (mean ± SE)
Group I	1.85 ± 0.04	1.85 ± 0.04	0.62±0.06	0.64±0.06
Group II	3.41 ± 0.18	3.49 ± 0.18	2.620±0.23	3.42±0.46
Group III	3.83 ± 0.29	**2.48 ± 0.29*** **	4.04±0.73	**2.21±0.12****

*OB- obesity, AT- Atorvastatin; I- Initial, Finally, **Statistically significant with $p < 0.05$;
***Statistically significant with $p < 0.001$ (paired t-test between before and after treatment values).

Table III was completed for all groups with lipid profiles and calculated Castelli risk index I and II and also, LCI. The values level of the lipid profile is evaluated with the standard logarithm of the molar ratio of the comprehensive lipid indexes, compared with single lipid parameters, such as non-HDL_C (TC minus HDL_C), TC/HDL_C-Castelli risk index I, LDL_C/HDL_C- Castelli risk index II and $TC*TG*LDL/HDL_C$ (Lipoprotein combine index, LCI).

In control groups, all the lipid index increased but was not statistically modified.

For group II, the obesity group with HFD (with 2%cholesterol) Castelli risk index I and II levels increased, not significantly and is correlated with food received, age, weight and without treatment administered. Therefore, Non-HDL_C novels were modified statistically significantly from 128.57±10.72 to 177.29±18.71. Also, the Lipoprotein Combine Index has the same, increased final levels of lipid profile from 32738.11±4776.05 to 43561.26±4996.11.

TABLE III.

Comparison for each study group before(initial) and after treatment(final) for CASTELLI RISK INDEX I and II, Lipoprotein combine index and Non-HDL_C. Values as Mean ± Standard error.

Parameter / Study group	TC/HDL_C **CASTELLI RISK INDEX I**		LDL_C/HDL_C **CASTELLI RISK INDEX II**		Non-HDL_C **(TC minus HDLc)**		TC * TG * LDL/HDL_C **LIPOPROTEIN COMBINE INDEX**	
	I	F	I	F	I	F	I	F

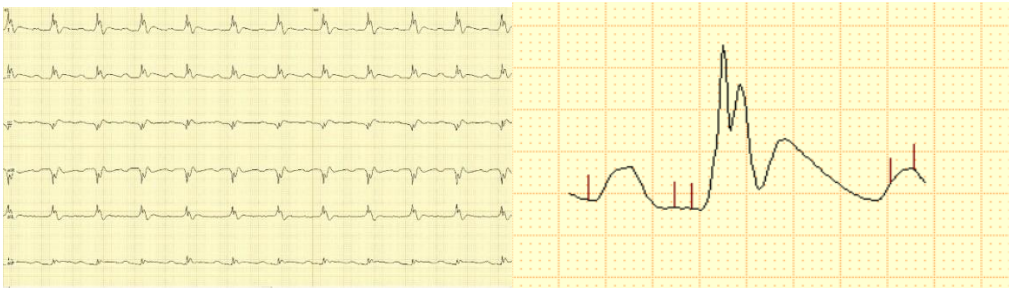
*OB- obesity, AT- Atorvastatin; **Statistically significant with p <0.05;
***Statistically significant with p < 0.001 (paired t-test between before and after treatment values).

In group III**,** which received treatment with statin, we observed significantly lower levels of TC, LDLc, and TG (tab. I). Also, AIP and lipoprotein combined index, TC/HDL_C and $TC * TG * LDL/HDL_C$ decreased statistically significantly with $p < 0.05$ in the final experiment.

As expected, the values of lipid profile - Castelli risk index I and II decreased statistically significantly from 5.04±0.73 to 3.21±0.12, 0.91±0.07 to 0.75±0.08 with statin treatment.

Finally, in the study, the recorded electrocardiograms did not reveal any pathological changes. EKG was performed on anesthetized subjects, induction with 5% isoflurane and maintenance with 2% isoflurane and 20 L/min oxygen (figs. 3, 4).

Abdominal ultrasonography performed during the present study revealed no structural changes, aortic wall thickness, atheroma plaque, or calcifications (fig. 5).



Figs. 3 and 4. Electrocardiogram performed in 6 leads, hex axial system; sinus rhythm, heart rate 400 bpm. P wave - 32 msec, 0.05 mV, PQ - 57 msec, R wave - 17 msec, 0.23 mV; QT - 88 msec, T - 0.19 mV. Calibration 200 mm/sec, 40 mm/mV.

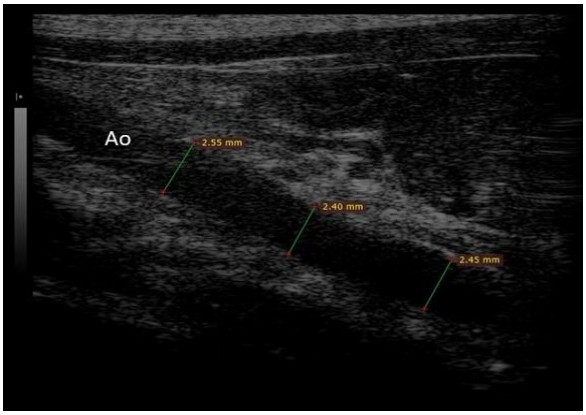


Fig. 5. Longitudinal abdominal aorta: example of aortic diameter measurement in systolic

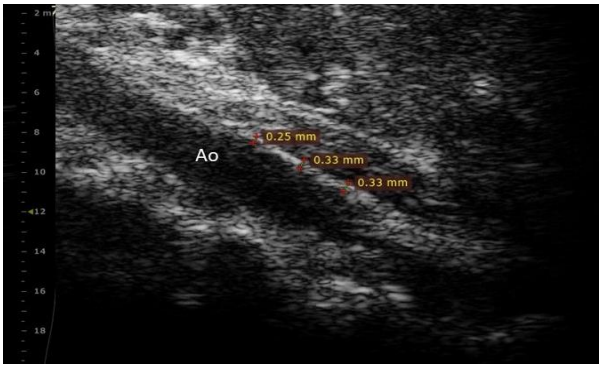

Fig. 6. Longitudinal abdominal aorta: example of aortic wall thickness measurement

Histological and structural characteristics

Slight aortic histomorphological modifications have been identified in the group with obesity *versus* the control group. All three groups have three distinct tunics: intima, media and adventitia. In all groups with obesity, the integrity of the endothelial layer was preserved but plaque for-

mation within the arteries was not seen in any group. In groups II and III, the histopathological aspect was modified for early endothelial injury (figs. 7, 8). In groups with obesity, the aorta wall with an asymmetrical thickness of tunica media with focal hypertrophy of tunica media, irregularly arranged elastic lamellae and slightly enlarged nuclei of smooth muscles, surrounded by adventitial fibrosis. Also, media thickening of the aortic wall, with an increase of collagen and a moderate amount of variably basophilic matrix extracellular matrix and many adipocytes in subjacent tunica adventitia in all groups (fig. 7).

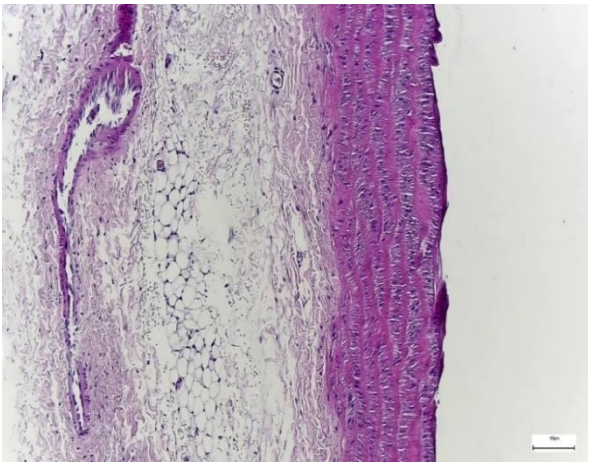

Fig. 8. Media thickening of the aortic wall, with an increase of collagen and a moderate amount of variably basophilic matrix extracellular matrix and many adipocytes in subjacent tunica adventitia (group 2 x10 HE)

DISCUSSION

Recently, AIP has been a strong marker for predicting the risk of cardiovascular diseases (18). According to previous studies, dyslipidemia is considered the most important factor for CVD. It is commonly known that standard lipid measurements, such as TC, LDL_C and TG, are associated with a significant risk for CVD events. Lipid ratios such as TC/HDL_C, LDL_C/HDL_C, LCI, AI and Castelli risk I and II are also considered to be a very important indicator of CVD. As a consequence, small-density LDL (sdLDL) is more easily oxidized to oxLDL and invades arterial deposits more easily than LDL because of the measure of particle size, it is very small. Macrophages become foam cells when oxLDL is phagocytized by macrophages, which influences arteriosclerosis and cardiovascular events.

Recent research has indicated that sdLDL is a significant predictor of arteriosclerosis and clinical application has been proposed. However, because it is a complex determination and has a high cost, the evaluation of sdLDL has limitations in clinical applications, AIP may be a good biochemical, economical and reliable indicator of coronary diseases and early stage of endothelial dysfunction.

Atherogenic Index of Plasma (AIP): In the present experiment, we observed that dyslipidemia in obesity groups, without treatment, increased the lipid profile, high AIP index, and lipoprotein combined index, then healthy controls but the summary clinical investigation is normal. In the present results, we discovered that in the obesity groups, the AIP value was more substantial than the values of controls (4.04±0.73 vs. 0.64±0.06). Also, the lipoprotein combine index decreased statistically significantly ($p < 0.05$) in group III (52008.64±6960.58 vs 16262.94±1445.30) and increased statistically significantly with ($p < 0.05$) in groups II- groups without treatment (32738.11±4776.05 *vs.* 43561.26±4996.11). To conform literature data and classification, we included Group II (with obesity) and Group III (obesity with statin treatment) in high risk for AIP. Furthermore, HDL_C contains an antioxidant enzyme and carries cholesterol from secondary tissues to the liver and is a component of the AIP. Decreased HDLc levels are associated with increased levels of pro inflammatory cytokines, TNF-alpha and interleukin-6 (19, 20) and can play an important role in the early stage of atherosclerosis. In our study level of HDL cholesterol was lower and can be improved with early treatment.

Date for literature reported the important effect of smoking, blood pressure, physical exercise and glycemia on AIP. Therefore, the authors reported a remarkable correlation between BMI, TC, and AIP in patients with cardiovascular diseases (21). In our experimental study, obesity and dyslipidemia can be the reason for high values of all parameters in the group with obesity.

In the present experimental study, will discover that all the lipid profiles were high values of the different atherogenic indices, Castelli risk and LCI. The ESC recommended, in primary prevention, to use of these lipid indexes and these parameters to evaluate and estimate the CVD risk (22).

Date from the literature confirmed several times the efficiency and benefits of treatment with a statin, in the experimental and clinical studies (23, 24, 25, 26,

27, 28, 29).

In an experimental study, animals with AIP height values and natural treatment have low-risk factors for atherosclerosis (30). Noor *et al.* show that in an experimental model of obesity rats, confirm that total cholesterol and LDL_C levels were positively correlated with the atherogenic index and treatment with methanolic extract in hyperlipidemic rats reduced the improved lipid profile and AIP (31). Lianto *et al* described that treatment with statin and high-dose Vitamin D improves levels of HDLc (32).

Previous epidemiologic studies on human subjects have shown contradictory results (5). For example, in a cross-sectional study, authors showed that the value of AIP was positively associated with waist circumference and body mass index and was inversely associated with physical activity (33). In the Turkish population-prospective study, AIP predicted CAD independently. Another study on human patients revealed that AIP was not an independent factor determining the impact of the risk of cardiovascular disease in postmenopausal women (34). In another prospective cohort study, authors evaluated the relationship between the AIP value and major adverse cardiovascular events during intensive hospitalization in patients with acute myocardial infarction (35).

Endothelial Dysfunction. Vascular endothelium has an important role in hemostasis and cardiovascular diseases. Obesity and dyslipidemia are the same, important factors for CVD because is accelerate atherosclerosis and increase cardiovascular risk. The current study used an experimental study to investigate the correlation that exists between AIP and endothelial dysfunction and compared the biochemical level of serum with histopathological aspects. In our research, we have found significantly high values of biochemical lipidic profile and AIP index, lipoprotein combines index compared with control groups. However, increased LDLc is another important marker of endothelial dysfunction since it can oxidize and generate oxidized Lipoprotein lipase cholesterol (LPL-cholesterol). This can increase the synthesis of caveolin-1, which inactivates eNOS and reduces NO production (36).

In our experimental study, non-efficient dyslipidemic profile control and high levels of LDLc can be considered the most important factors for endothelial dysfunction in obesity rats.

Lipid Profile. In practical terms, we know that dyslipidemia constitutes an important risk for CVD. Our results observed that group III who received treatment with Atorvastatin 20mg/day by gavage, profile lipid, AIP, atherogenic index, Castelli index and also lipoprotein combined index decreased significative statistically.

Abdominal and carotid ultrasonography in our results confirm that calcification and atherogenic plaque are too early to see. In daily practice, it's an investigation basically, but not relevant to endothelial dysfunction in the incipient stage.

The histopathological aspect of the abdominal aorta confirmed that dyslipidemia induced and determined incipient modified for endothelial injury, vascular endothelium is affected with asymmetrical thickness of tunica media, focal hypertrophy of tunica media, also, irregularly arranged elastic lamellae, slightly enlarged nuclei of smooth muscles, surrounded by adventitial fibrosis. Our study confirmed the associa-

tion between biochemical and histopathological aspects can be an early stage of atherosclerosis.

High AIP was the most common abnormality among the atherogenic indices (37) in practice. According to our results, AIP can be more easily applied in practice than other lipid ratios and traditional lipid indicators. It was also found that AIP can be a substantial predictor of the probability of cardiovascular disease. Prevention and early treatment for dyslipidemia can improve the lipid profile, Atherogenic Index of Plasma, lipoprotein combined index, Castelli index and endothelial function.

Our research concluded that the AIP, atherogenic coefficient (AI), Lipoprotein combined index (LCI) or Castelli's risk indices I and II can be powerful biochemical predictors of early endothelial dysfunction and cardiovascular diseases in the experimental group with obesity. Therefore, the AIP can be usually calculated in medical practice, using only a standard lipid profile, making it an easily, economical and accessible biomarker (38).

CONCLUSIONS

The prevention of cardiovascular disease remains the main objective of modern medicine and a controversial issue. Our study confirms that the AIP can be a better biochemical predictor for endothelial dysfunction and atherosclerosis, than individual cholesterol risk factors and also a good predictor of cardiovascular risk. As a result, we believe that the AIP can significantly improve the cardiovascular disease risk algorithm. Furthermore, a reduction in AIP values, which includes lowering LDLc levels, might be a crucial part of the therapy for dyslipidemia.

CONFLICTS OF INTEREST AND FUNDING

The authors declare there is no conflict of interest. This experimental study was supported by "Grigore T. Popa" University of Medicine and Pharmacy, by Andreea Clim as a Ph.D. researcher, with the supervision of Professor Ionela Lăcrămioara Şerban, M.D., Ph.D., and was effectuated in accord and supported by Advanced Research and Development Center in Experimental Medicine (CEMEX), "Grigore T. WOMEN'S ANXIETY AND PERCEPTIONS OF PAP TESTS IN NORTH-EASTERN ROMANIA (Abstract): Cervical cancer is still a substantial global public health issue among women. In the prevention and early diagnosis, cervical cancer screening plays a crucial role (1). However, acceptance of and participation in this screening are influenced by various factors. Woman's psychological status, including stress, anxiety, depression, or individual perception of health, can influence the decision to participate in cervical cancer screening. The current study **aimed** to investigate the psychological impact of Papanicolaou (Pap) testing in women in the North-eastern Romania. **Materials and methods:** This study was conducted using a questionnaire specifically developed for this study, which included structured questions aimed to assess various aspects of the psychological impact of cervical cancer screening. The statistical analysis for this study was performed using *IBM SPSS Statistics* version 26. **Results:** The study indicated a significant positive association between the perception that the Pap test was painful and anxiety related to unfavorable results and fertility concerns fertility. Younger women tend to have their Pap test more often than older women. Women with previous negative Pap test results tend to have lower levels of anxiety related to unfavorable results compared to women previously experiencing positive Pap test results. The results indicated that the regression model (i.e., age, perceptions about the Pap test - cost, pain, and embarrassment) did not significantly predict the anxiety related to unfavorable results. **Conclusions**: Our study highlights important psychosocial aspects related to cervical cancer screening and provides a foundation for improving health promotion services and risk awareness programs. **Keywords:** ANXIETY, DEPRESSION, PAP TEST, CERVICAL CANCER, CERVICAL SCREENING.

INTRODUCTION

Cervical cancer is a significant global public health problem, particularly affecting women. In the area of prevention and early diagnosis, cervical cancer screening plays a crucial role (1). In developed countries, routine screening schedules with Pap tests and/or HPV tests have led to a drastic decrease in the incidence and mortality of cervical cancer over the past five decades. In Romania, in 2020 alone, 3380 women were diagnosed with cervical cancer and 1805 died from this disease, while the 5-year prevalence was 9808 cases, according to Globocan data (2). Romania has the lowest rate of cervical cancer screening attendance

in the EU, influenced by specific social connotations. Thus, in 2019, less than 30% of Romanian women reported having had a Pap test in the last three years, which is half the European average (3). However, acceptance and participation in this screening are influenced by a variety of factors, which can be grouped into three main categories: awareness of the disease and the need for screening, structural barriers, and psychosocial beliefs about the disease and screening. Despite advances in the medical field, socio-psychological factors, particularly the psychological status of women, can significantly impact the effectiveness and participation in such screening programs. A woman's psychological status, including stress, anxiety, depression, or self-perceived health, can influence her decision to participate in cervical cancer screening. Concerns about pain, discomfort, or embarrassment associated with the procedure, or negative past experiences can discourage participation in the screening (4-7).

Discomfort with the attitude of healthcare workers, fear of being labeled, fear of being diagnosed with cancer and the implications of this diagnosis, fear of stigma, embarrassment, unacceptable touch, and negative experiences with the healthcare system can be significant psychological barriers to screening participation (8). Also, studies have highlighted that abnormal Pap smear findings evoke negative emotions ranging from anxiety to fear of developing or even having cancer (9-12).

The current study aimed at investigating the psychological impact of undergoing a Papanicolaou (Pap) test experienced by women in North-eastern Romania. This research was motivated by the need to understand how various factors influence women's experiences and perceptions related to Pap test, a critical screening tool for cervical cancer. Specifically, this study examined the interplay between age, perceptions of the Pap test (regarding cost, pain, and embarrassment), timing of the last test (within the last 2 years, between 2 and 5 years, more than 5 years ago), anxiety related to potentially unfavorable results, and fertility concerns.

OBJECTIVE AND HYPOTHESIS

The main objective of the present study was to comprehensively evaluate the psychological impact of Pap testing in women, focusing on the relationship between age, perceptions of the test (cost, pain, and embarrassment), timing of the last test, anxiety related to potentially unfavorable results, and concerns about fertility. Therefore, the current study was conducted to analyze the following hypotheses:

H1. There is a significant positive relationship between age, last test, result (positive, negative), perceptions of the test (cost, pain, and embarrassment), and anxiety related to potentially unfavorable results.

H2. There is a significant positive relationship between age, last test, result (positive, negative), perceptions of the test (cost, pain, and embarrassment), and concerns about fertility.

H3. Significant differences exist between age groups regarding the timing of the last Papanicolaou test.

H4. Women who received a positive result from a previous Pap test will experience a higher level of anxiety related to potentially unfavorable results compared to those receiving a negative result.

H5. There are significant differences in fertility-related concerns between women who received a negative result and women who received a positive result from a previous Pap test.

H6. Age and perceptions of the Pap test

(cost, pain, and embarrassment) significantly predict anxiety related to potentially unfavorable results.

H7. Age and perceptions of the Pap test (cost, pain, and embarrassment) significantly predict concerns about fertility.

MATERIALS AND METHODS

Participants and procedure

The study was conducted using a questionnaire specifically developed for this study, which included structured questions to assess various aspects of the psychological impact of cervical cancer screening. The target population were women (N = 308) aged 18-70 years old, 68.8% aged 25-45 and 27.3% aged 45-65 years old, who either participated (90.3%) or did not participate (9.7%) in cervical cancer screening programs, the selection being random. Moreover, 88.6% of participants who had previously undergone a Pap test received a negative result, while 4.9% received a positive result.

Recruitment into the study involved inviting eligible women to participate through online invitations, providing them with information about the purpose of the study, and obtaining their consent to participate. Data were collected using the Google Forms platform.

Measures

To measure the research variables, specific questions tailored to the topics of interest for the current research were used.

Anxiety related to unfavorable result

To measure anxiety related to potentially unfavorable results, we asked the participants to rate on a 4-point Likert scale, from 1 (not at all) to 4 (very much), how anxious they felt about the possibility of an unfavorable result.

Fertility concerns

To measure concerns about fertility, we used the same approach as we did to measure anxiety related to unfavorable results.

Demographic data

We asked participants to indicate their age group (18-25, 25-45, 45-65, and over 65), area of residence (rural or urban), educational level, and relationship status.

Statistical Analysis

For this study, the statistical analysis was conducted using *IBM SPSS Statistics* version 26. Our primary goal was to explore the psychological impact of undergoing a Papanicolaou (Pap) test on women, considering various influencing factors. The analyses were focused on the following variables: age, perceptions of the Pap test (regarding cost, pain, and embarrassment), timing of the last test (within the last 2 years, between 2 and 5 years, more than 5 years ago), anxiety related to potentially unfavorable results, and concerns about fertility.

First, descriptive statistics were used to summarize the demographic characteristics of the sample and the distribution of responses for each variable. Moreover, Spearman's correlation coefficients were computed to examine the relationship between age and perceptions of the Pap test (cost, pain, and embarrassment). To compare the psychological impact across different groups, we used One-Way ANOVA and Independent Samples t-Tests to analyze the differences between age groups and last Pap test (within the last 2 years, between 2 and 5 years, more than 5 years ago), and to compare differences in anxiety level and fertility concerns based on the Pap test result (in those who underwent a Pap test before). However, multiple regression analyses were performed to assess the predictive power of age, perceptions of the Pap test (regarding cost, pain, and embarrassment), and timing of the last test (within the last 2 years, between 2 and 5 years, more than 5 years ago)

on anxiety related to unfavorable results and fertility concerns.

RESULTS

The Spearman correlation analysis indicated a significant positive association between the perception that the Pap test is painful and anxiety related to unfavorable results (r = .196, p = .004). Thus, the higher the perception that the Pap test as being painful, the higher the anxiety related to unfavorable results. Moreover, the results indicated a significant positive relationship between the perception that the Pap test is being painful and fertility concerns (r = .136, p = .038). Thus, the higher the perception that the Pap test is painful, the higher the concern about fertility. Therefore, women who experience Pap smear pain had fertility concerns (tab. I).

Note *p< .05; **p<.01

One-Way ANOVA compared the means and revealed significant differences between age groups and last Pap test (within the last 2 years, between 2 and 5 years, more than 5 years ago) (F (3; 282) = 6.63, p = .000). Specifically, significant differences were found between the 25-45 age group (M = 1.34, SD = .58) and 45-65 age group (M = 1.69, SD = .77) regarding the last Pap test (within the last 2 years, between 2 and 5 years, more than 5 years ago). Participants in the 45-64 age group tend to have had their last Pap test longer ago compared to those in the 25-45 age group. Thus, younger women tend to have their Pap test more often than older women (tab. II).

TABLE II.

One-way ANOVA analysis

Last Pap test	Sum of Squares	df	Mean Square	F	p
Between Groups	8.19	3	2.73	6.63	.000
Within Groups	116.04	282	.412		
Total	124.23	285			

The Independent t-Test results indicated significant differences in anxiety related to unfavorable result (t (251) = -2.25, p = .025) between the participants who had previously

undergone a Pap test and received a negative result (M = 1.93, SD = .80) and those who received a positive result (M = 2.45, SD = 1.05), with higher levels of anxiety in those who received a positive result. Thus, women who previously received negative results from the Pap test tend to have lower levels of anxiety related to unfavorable results compared to women who previously received positive results from the Pap test (tab. III).

TABLE III.

Independent t-test for anxiety

Anxiety	**N**	**M**	**SD**	**t-test**	**p**
Negative result	240	1.93	.80	-2.25	.025
Positive result	13	2.46	1.05		

TABLE IV.

Independent t-test for fertility concerns

Fertility concerns	**N**	**M**	**SD**	**t-test**	**p**
Negative result	240	2.63	1.26	-1.57	.117
Positive result	15	3.20	1.26		

Regression results indicated that the regression model (i.e. age, perceptions of the Pap test - cost, pain, and embarrassment) did not significantly predict anxiety related to unfavorable results ($F (4, 205) = 1.55$, $p > .05$). Moreover, no independent variable was a significant predictor.

Also, regression results indicated that the regression model (i.e., age, perceptions of the Pap test - cost, pain, and embarrassment) did not significantly predict the fertility concerns ($F (4, 212) = .97$, $p > .05$). Moreover, no independent variable was a significant predictor.

Thus, the regression model, which relates age and perceptions of the Pap test (cost, pain, embarrassment) does not significantly predict anxiety related to an unfavorable result.

Finally, regression results indicated that the regression model (i.e., age, perceptions of the Pap test - cost, pain, and embarrassment) did not significantly predict fertility concerns ($F (4, 212) = .97$, $p > .05$). Moreover, no independent variable was a significant predictor. Thus, the regression model, which relates age and perceptions of the Pap test (cost, pain, embarrassment), does not significantly predict fertility concerns (tab. V).

Hypothesis testing - brief results

H1. There is a significant positive relationship between age, last test, result (positive, negative), perceptions of the test (cost, pain, and embarrassment), and anxiety related to potentially unfavorable results.

Results indicated a significant positive association between the perception that the Pap test is painful and anxiety related to unfavorable results ($r = .196$, $p = .004$).

H2. There is a significant positive relationship between age, last test, result (positive, negative), perceptions of the test (cost, pain, and embarrassment), and fertility concerns.

Results indicated a significant positive relationship between the perception that the Pap test is painful and fertility concerns ($r = .136$, $p = .038$).

H3. Significant differences exist between age groups regarding the timing of the last Papanicolaou test.

There are significant differences between age groups and last Pap test (within the last 2 years, between 2 and 5 years, over 5 years) ($F (3; 282) = 6.63$, $p = .000$).

H4. Women who received a positive result from a previous Pap test will have higher anxiety related to potentially unfavorable results compared to those who received a negative result.

Results indicated significant differences ($t (251) = -2.25$, $p = .025$) between participants who had previously undergone a Pap test and received a negative result ($M = 1.93$, $SD = .80$) and participants who received a positive result ($M = 2.45$, $SD = 1.05$) regarding anxiety related to unfavorable result, with the participants who received a positive result experiencing higher anxiety compared to those who received a negative result.

H5. There are significant differences in fertility concerns between women who received a negative result and women who received a positive result from a previous Pap test.

Results indicated that there are no significant differences in fertility concerns ($t (283) = -1.57$, $p = .11$).

H6. Age and perceptions of the Pap test (cost, pain, and embarrassment) will significantly predict anxiety related to potentially unfavorable results.

Results indicated that the regression model (i.e., age, perceptions of the Pap test - cost, pain, and embarrassment) did not significantly predict anxiety related to unfavorable results ($F (4, 205) = 1.55$, $p > .05$).

H7. Age and perceptions of the Pap test (cost, pain, and embarrassment) will significantly predict fertility concerns.

Results indicated that the regression model (i.e., age, perceptions of the Pap test - cost, pain, and embarrassment) did not significantly predict fertility concerns ($F (4, 212) = .97$, $p > .05$).

DISCUSSION

This research was conducted to understand how various factors impact women's experiences and perceptions regarding Pap testing, a crucial screening tool for cervical cancer. We analyzed a sample of 307 women, exploring their distribution according to various factors. Most participants (68.95%) were in the 25-45 years age group, corresponding to the socially active population and the most likely to develop this condition. The results of previous studies show that psychological response to Pap test is a significant barrier to screening for women of all ages (11, 13), including those who had never undergone screening (14, 15). Results showed that older women more often face emotional barriers than practical barriers, while younger women more often advocate practical barriers (16). Our study

supports this hypothesis: participants in the 45-64 years age group tend to have had their last Pap test after a longer time interval compared to those in the 25-45 age group. Thus, younger women tend to have their Pap test more often than older women. Similar studies consider the same results to be influenced by public health campaigns and guideline recommendations (17). Regarding the lower rate of Pap tests in the older women group, several studies have identified a trend where older women tend to have Pap tests less frequently than younger women (18, 19).

We found significant variations in the time interval since last test. A significant percentage of the participants performed the regular test over the last 2 years, indicating continued attention to reproductive health. This group can benefit from early detection and regular health monitoring. At the same time, 24.6% of these women participated in the screening 2-5 years ago, and this may indicate a possible concern about the frequency of the tests or reflect individual circumstances such as limited access to medical services. It is also important to pay attention to the 9.5% of the participants who had the test more than 5 years ago. This group may be at increased risk, and this finding may serve as a basis for developing specific awareness and intervention strategies to stimulate participation in regular screening. A personalized and educational approach can be crucial to improving participation in screening and reducing the risk of reproductive health complications among participants.

Regarding the association between the perception that the Pap test is painful, and anxiety is related to unfavorable results, the higher the perception that the Pap test is painful, the higher the anxiety related to unfavorable results. Thus, the higher the perception that the Pap test is painful, the higher the fertility concern. Therefore, women who felt pain when they did the Pap test had fertility concerns. An explanation for this result can be that when women experience pain during the Pap test, their anxiety about potential abnormal findings (e.g. cervical cancer) increases, leading to fears about subsequent treatments that could affect their reproductive health.

Therefore, women who previously had negative Pap test results tend to have lower levels of anxiety related to unfavorable results compared to women who previously had positive Pap test results. An explanation can be that women with previous negative results may perceive themselves at a lower risk for cervical abnormalities, and this fact may contribute to a low level of anxiety while those who have previously received positive results may consider themselves likely to have unfavorable outcomes. This heightened anxiety among women with previous positive results could be due to the psychological impact of past experiences, highlighting the need for psychological support and counseling in such cases.

Our findings are consistent with previous studies showing that a positive HPV result in combination with abnormal cytology is associated with increased anxiety and stress (20-23). As reported in literature, women's experiences during a Pap test are diverse. Some women experience embarrassment, anxiety, intimidation, and fear. In particular, fear is related to the belief that knowledge of a negative diagnosis can accelerate the course of cancer (4-7). Frederiksen *et al.* have published a very detailed review (24), which summarized data from 16 studies examining psychological

out-comes in women with histologically diagnosed or treated cervical intraepithelial neoplasia or cervical cancer. One of the key findings was that the psychological outcome of women with cervical intraepithelial neoplasia was similar to those of women with abnormal cytology but not necessarily needing treatment. They interpreted this finding as a consequence of women's uncertainty about their disease status. Frederiksen *et al.* also saw that women considered a cervical intraepithelial neoplasia diagnosis to be as bad as that of cervical cancer (25).

Another study from 2020 examining short-term anxiety and distress in women receiving different results following routine human papillomavirus (HPV) primary testing at cervical screening found evidence that clinically significant levels of anxiety may be more common in women who do not understand their result or received a positive one (26, 27).

When comparing participants who had a previous Pap test and received a negative result, there were no significant differences in fertility concerns. This finding implies that factors other than test results, possibly including personal beliefs and broader reproductive health education, might influence fertility concerns.

Other variables such as age, cost, pain, and embarrassment were not individually associated with increased anxiety from a negative result or fear of infertility. This indicates that none of these variables significantly contribute to anxiety or fertility concerns when considered separately. Models including age and perceptions of the Pap test (cost, pain, embarrassment) did not significantly predict anxiety related to unfavorable results or fertility concerns. Thus, the model, which includes age and perceptions of the Pap test (cost, pain, embarrassment), does not significantly predict anxiety related to unfavorable results.

Finally, the results indicated that the model age and perceptions of the Pap test (cost, pain, and embarrassment) did not significantly predict fertility concerns. This suggests that other variables or factors not considered might play a more significant role in these aspects. All these variables can collectively generate anxiety in the context of inadequate screening or absence of appropriate informative programs. The lack of accurate information and education regarding the Pap test can amplify fears related to cost, pain, embarrassment, and negative results. In this respect, informative programs that clearly explain to the population the role of this screening, how results are interpreted, and the available treatment options are essential.

Education and awareness can reduce anxiety and fertility concerns. Clear and accessible information can help demystify the Pap test and reduce the associated shame and fears. This can lead to better acceptance and participation in the screening, thus reducing overall anxiety related to the process and its results. Studies have shown that women who had never undergone the screening are more likely to report shame and anxiety as barriers, while those who underwent the screening are more likely to quote lack of time as a barrier. Worry is a key barrier to participation in the screening among women who had largely not undergone prior screening (14). The lack of adequate knowledge is recognized as an important barrier and a significant impediment (28, 29). Lack of knowledge of the disease process or the benefits of screening not only prevents women from initiating the decision-making

process related to participation in the screening (27) but could also generate fear of the disease or screening procedure

CONCLUSIONS

In conclusion, our study highlights important psychosocial aspects of cervical cancer screening and provides a foundation for improving health promotion services and risk awareness programs. Anxiety has been shown to be a decisive factor associated with the fear of a negative result or potential fertility issues. Therefore, the non-participation in the screening is not driven by pain, embarrassment, or costs but is fundamentally rooted in the fear of a possible unfavorable result. Although individual variables such as age, cost, pain, and embarrassment do not significantly predict anxiety or fertility concerns and are undoubtly associated with a positive test result, adequate screening and well-structured informative programs are essential to reduce anxiety and improve Pap test acceptability.

The practical implications of this research could enhance the effectiveness of screening and reduce the negative psychosocial impact on patients. Psychosocial barriers to screening may most significantly interfere with initial and timely screenings; specifically, directly addressing these barriers can encourage women to undergo screening for the first time or in a timely manner, leading to early diagnosis of this condition before it progresses to cancer.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

DIAGNOSIS AND MANAGEMENT CHALLENGES OF PLACENTA ACCRETA SPECTRUM DISORDERS (Abstract): Placenta accreta spectrum (PAS) disorders are associated with significant maternal and neonatal morbidity and mortality. The primary aim of this study was to determine the diagnostic accuracy of individual and combined ultrasound markers for predicting PAS disorders and to report the intraoperative complication rates for this category of patients. The secondary aim of this study was to reflect the clinical challenges of a case diagnosed with placenta accreta. **Materials and methods**: We conducted a retrospective analysis of clinical and ultrasound data from 52 pregnant patients with or without confirmed PAS disorders who gave birth in a tertiary center. Univariate analysis was used to compare differences in baseline characteristics between groups. We calculated the diagnostic accuracy of ultrasound signs for PAS disorders and the complication rates in these patients. **Results**: Placental lacunar spaces had a sensitivity of 83.87%, a specificity of 76.19%, and an accuracy of 80.77% for predicting PAS disorder. The best predictive performance for predicting PAS disorders was achieved when using at least three ultrasound markers, with a sensitivity of 90.32%, a specificity of 85.71%, and an accuracy of 88.46%. Urinary tract injuries were the most frequently encountered complications in patients with confirmed PAS. **Conclusions:** Better antenatal diagnosis of this pathology will reduce the surgical risk and improve the overall outcome for both mother and fetus. **Keywords:** PLACENTA ACCRETA, CAESAREAN SCAR, PREGNANCY, ULTRASOUND, DOPPLER.

INTRODUCTION

The term "placenta accreta" refers to abnormal placental adherence, as well as a pathology that appears on echography and resembles an abnormal placental spectrum (1). Placenta percreta, a rarer pathology, is

linked to high mortality and blood loss due to potential hematuria during pregnancy, early labor onset, and significant neonatal comorbidities (2). The incidence of abnormal placental adherence varies from 1/110 to 1/2500 of deliveries (3). With increasing rates of elective cesarean section, the risk of this pathology has increased more than fivefold (4). Studies show that by evaluating these placental anomalies with the help of the ultrasound, we can detect this pathology at around 28 weeks of gestation, giving us enough time to prepare strategically for the surgery and also to emotionally prepare the patient (5, 6).

MRI is considered mandatory after 32 weeks of gestation for the better visualization of placental abnormalities and reduction of fetal developmental exposure (7).

A full bladder is usually necessary for better visualization of the lower anterior uterine wall. The ultrasound markers such as the placental position, placental thickness, the presence/absence of the retroplacental space, the thickness of the retroplacental myometrium, the bladder line interruption, the presence/absence of the placental lacunae, the retroplacental myometrial blood flow, the presence/absence of a cervical sinus, and the cervical morphology are recorded (8).

Placental thickness and retroplacental myometrial thickness are measured by placing the ultrasound probe perpendicular to the uterine wall. The abnormal vessels have a Doppler blood flow velocity exceeding approximately 20 cm/s (9).

The ultrasound markers for PAS disorders include: loss of the clear zone, which could be described as the absence of the normal hypoechoic area between the placenta and the uterine wall; placental lacunae, which are described as irregular vascular spaces within the placenta; bladder wall interruption, which is described as a disruption of the bright echogenic line representing the bladder wall; uterovesical hypervascularity and increased vascularity in the parametrial region visible on color Doppler ultrasound (10). Accurate identification of these markers helps in the prenatal diagnosis of PAS and aids in planning the management to minimize risks during delivery (11, 12).

Choosing a stress-free time for delivery and planning cesarean section at approximately 35 weeks +/- 2 weeks are also important factors for both the maternal and fetal survival (13, 14).

The antenatal course of corticosteroid injections is helpful in promoting fetal lung development (15).

A multidisciplinary team is recommended for pre-operative planning, preordering of blood, and the availability of a urology team if necessary (16). If there is a high suspicion of a percreta, an ureteral catheter is recommended in case of further bladder dissection during surgery (17).

Associated coagulopathies and periportal hemorrhage (PPH) are often responsible for the high morbidity and mortality of “Placenta Accreta Spectrum” (PAS). The anesthesia team requires prepared blood transfusions and correction factor products in order to manage hypovolemia and coagulopathy (18, 19).

The aim of this study was to determine the diagnostic accuracy of individual and combined ultrasound markers for the prediction of PAS disorders and to report the intraoperative complication rates in this group of patients. The secondary aim of this study was to reflect the clinical challenges of a case diagnosed with placenta accreta.

MATERIALS AND METHODS

We conducted a retrospective analysis of the medical records of pregnant patients, with or without confirmed PAS disorders, who delivered at "Cuza-Vodă" Clinical Hospital of Obstetrics and Gynecology of Iasi, Romania, between January 2019, and December 2023. Exclusion criteria included the following: incomplete medical records, non-viable pregnancies, multiple gestations, unavailable ultrasound data, and concurrent major health conditions that could affect pregnancy outcomes, unrelated to PAS.

Approval to access the hospital database was granted by the Institutional Ethics Committee of "Cuza-Vodă" Clinical Hospital of Obstetrics and Gynecology (No. 2461/25 February 2022). Data from a total of 52 patients were included in the analysis considering the following groups: PAS positive (n= 31 patients) and PAS negative (n= 21 patients).

The type of data retrieved from the medical records included the intraoperative confirmation of PAS disorders, ultrasound evidence of PAS disorders and intraoperative or postoperative complications. We also collected data on the demographic characteristics of the study cohort, along with data regarding specific clinical risk factors (number of previous cesarean deliveries, age, BMI, smoking status, parity, and interpregnancy interval).

The chi-squared test was used to assess between-group differences in categorical variables, and the *Student t-test* was used to assess between-group differences in continuous variables. A p-value less than 0.05 was considered statistically significant.

Using this type of data, we calculated the diagnostic accuracy of ultrasound signs for PAS disorders, reporting sensitivities (Se), specificities (Sp), positive and negative likelihood ratios (LRs), and complication rates in patients with confirmed PAS disorders. Statistical analyses were performed using STATA SE (version 18.5, *Stata Corp LLC*. College Station, TX, United States of America).

RESULTS

First table shows the comparisons between the groups with respect to their demographic and clinical characteristics. Our groups were relatively homogenous regarding the following parameters: living environment (p= 0.69), mean age at diagnosis (p= 0.48), obesity rate (p= 0.45), and smoking status before and/or during pregnancy (p= 0.67).

On the other hand, our data indicated that patients with confirmed PAS disorders had significantly higher parity (2.22 ± 1.49 *vs.* 1.57 ± 0.87, p= 0.03) compared to patients with unconfirmed PAS diagnosis.

Moreover, the first group had a significantly higher number of previous cesarean deliveries (2.03 ± 0.70 *vs.* 1.57 ± 0.59, p= 0.01), and a significantly shorter interpregnancy interval compared to the second group (0.94 ± 1.44 *vs.* 1.82 ± 1.55, p= 0.02) (tab. I).

The diagnostic accuracy of ultrasound signs for the detection of PAS disorders is presented in Table II. Our results showed that placental lacunar spaces had a sensitivity (Se) of 83.87%, a specificity of 76.19% and an accuracy of 80.77% for predicting PAS disorder.

High sensitivities were also achieved by myometrial thinning of less than 1 mm (80.65%) and loss of retroplacental clear zone (80.65%), which achieved accuracies of 76.92% and 71.15%, respectively.

On the other hand, the highest specificities (Sp) were achieved by bladder wall

interruption (90.48%), placental bulging (85.71%) and hypervascularity of the uterovesical or retroplacental space (85.71%), which were reflected in high positive likelihood ratios of 6.774, 4.064 and 3.839, respectively.

TABLE I.

Comparisons of baseline characteristics between groups.

Patient's Characteristics	Pas Positive (n = 26)	Pas Negative (n = 13)	*p* Value
Living environment (n/%)	Rural= 15 (48.39%) Urban= 16 (51.61%)	Rural= 9 (42.86%) Urban= 16 (57.14%)	0.69
Age (years, mean ± SD)	30.48 ± 7.21	30.57 ± 5.06	0.48
Obesity (n/%)	12 (38.71%)	6 (28.57%)	0.45
Smoking status (n/%)	9 (29.03%)	5 (23.81%)	0.67
Parity (mean ± SD)	2.22 ± 1.49	1.57 ± 0.87	0.03
Number of previous CS (mean ± SD)	2.03 ± 0.70	1.57 ± 0.59	0.01
Interpregnancy interval (years, mean ± SD)	0.94 ± 1.44	1.82 ± 1.55	0.02

PAS - placenta accreta spectrum, SD- standard deviation, CS- cesarean section.

TABLE II.

The predictive performance of individual and combined ultrasound markers for predicting PAS disorders.

Ultrasound Signs	Se	Sp	Accuracy	+LR	-LR
Placental lacunar spaces	83.87%	76.19%	80.77%	3.5226	0.2117
Loss of retroplacental clear zone	80.65%	57.14%	71.15%	1.8817	0.3387
Bladder wall interruption	64.52%	90.48%	75%	6.774	0.3922
Myometrial thinning < 1 mm	80.65%	71.43%	76.92%	2.8226	0.2709
Placental bulging	58.06%	85.71%	69.23%	4.0645	0.4892
Bridging vessels	77.42%	66.67%	73.08%	2.3226	0.3387
Hypervascularity of the uterovesical or retroplacental space	54.84%	85.71%	67.31%	3.839	0.5269
≥3 US signs present	90.32%	85.71%	88.46%	6.323	0.1129

Legend: Se- sensitivity, Sp- specificity, +LR- positive likelihood ratio, - LR- negative likelihood ratio, US- ultrasound.

The best predictive performance for predicting PAS disorders was achieved when using at least three ultrasound markers. In this scenario, the Se was 90.32%, the Sp was 85.71%, and the accuracy was 88.46%, with a positive likelihood ratio of 6.323 and a

negative likelihood ratio of 0.112 (tab. II).

Table III shows the documented complication rates for patients with a confirmed diagnosis of PAS disorders. Our data indicated that the majority of these patients (74.19%) underwent total hysterectomy, while the subtotal hysterectomy was performed in only 22.58% of these patients.

Urological complications such as urinary bladder injury (48.38%) and ureteral injury (25.80%) were common and required multidisciplinary collaboration with urologists. In addition, significant intraoperative blood loss was documented in 32.25% of these patients, who benefited from blood transfusions (tab. III).

TABLE III.

The complication rates in patients with PAS disorders.

Complications	Rates	
	Yes (n, %)	No (n, %)
Total hysterectomy	23 (74.19%)	8 (25.80%)
Subtotal hysterectomy	7 (22.58%)	24 (77.41%)
Intraoperative urinary bladder injury	15 (48.38%)	16 (46.2%)
Intraoperative ureteral injury	8 (25.80%)	23 (73.1%)
Necessity of blood transfusion	10 (32.25%)	21 (67.74%)

Legend: number of transfusions.

DISCUSSION

Placenta accreta spectrum (PAS) refers to the abnormal adhesion or invasion of trophoblastic tissue into the myometrium. This pathology causes significant maternal morbidity such as uterine rupture, severe postpartum hemorrhage, multiple organ failure, and preterm delivery. Ultrasound is the preferred screening tool for PAS and can reduce obstetric morbidity in women at risk (20).

Our results showed that placental lacunar spaces, myometrial thinning of less than 1 mm and bladder wall interruptions achieved the highest accuracy in predicting PAS disorders. Moreover, the best predictive performance for predicting PAS disorders was achieved when using at least three ultrasound markers. These results are consistent with previously published data.

A Delphi survey and consensus published in 2023 found that only 7 ultrasound markers are relevant for PAS screening in mid-gestation in patients with a previous history of at least one cesarean delivery, myomectomy or PAS: loss of the ‘clear zone’, myometrial thinning, bladder-wall interruption, placental bulge, uterovesical hypervascularity, placental lacunae and bridging vessels (21).

A review of more than 20 studies and 3,000 pregnancies revealed that ultrasound can be considered an overall good diagnostic tool for identifying the depth of the placental invasion. The sensitivity of the uterovesical hypervascularity was low for the detection of placenta accreta. but was important for the identification of placenta increta or percreta, thus making it an important marker for the prediction of this subtype (22, 23).

In a prospective study, there were evaluated women with placenta previa and a history of at least one prior cesarean section or myomectomy. The analyzed ultra-

sound markers included the loss of the clear zone, placental lacunae, bladder wall interruption, uterovesical hypervascularity, and increased parametrial vascularity (24). When at least one sign was used, the ultrasound showed very good sensitivity. The use of three ultrasound signs has improved the detection rate of placenta percreta, highlighting the importance of considering as many markers as possible to improve surgical preparation (24, 25).

Another study analyzed the outcomes for women with placenta accreta when diagnosed antenatally or intrapartum. Women who were suspected of having PAS antenatally had a lower estimated blood loss, with a median of 4 l, and required fewer units of packed red blood cells transfusion. Coagulation testing and its results are critical not only for high-risk patients, but also for those at extreme ages, such as teenage pregnant women, who are preparing for either a vaginal delivery or a caesarean section (26).

A recent prospective cohort study conducted by Sargent *et al*., tested the predictive performance of a model based on ultrasound markers for predicting cases that will develop abnormally adherent or invasive placentation (27). The included ultrasound parameters were represented by loss of clear zone, abnormal placental lacunae, placental bulge and bladder wall interruption, and had an accuracy of 0.901.

A retrospective cohort study conducted in seven centers evaluated the performance of classic ultrasound signs for the detection of PAS using data from a total of 385 cases (28). The authors considered the classical ultrasound markers of PAS as placental lacunae, bladder-wall interruption, myometrial thinning and sub placental hypervascularity, and the following novel signs: small placental lacunae, irregular placenta-myometrium interface (PMI), vascular PMI, non-tapered placental edge and placental bulge toward the bladder.

The authors demonstrated that the model based on classical ultrasound markers achieved an AUROC (areas under the receiver operating curve) value of 0.81, while the model based on novel ultrasound markers achieved an AUROC value of 0.84 (28). Moreover, a model combining both types of ultrasound markers had an AUROC value of 0.88, suggesting that the use of multiple ultrasound markers could better predict the occurrence of PAS disorders. Thus, the imaging techniques are effective in antenatal risk stratification (29-32).

It is well known that PAS disorders are associated with complex urological complications, often requiring surgical repair (33, 34, 35). In our study, urological complications such as urinary bladder injury and ureteral injury were common and required multidisciplinary collaboration with urologists. A recent systematic review published in 2023 evaluated the rates of urological complications in patients diagnosed with PAS disorders using data collected from 6 studies (36). The authors showed that the overall rate of urological complications was 15.2%. Urological complications were encountered in 19.4% of cases undergoing hysterectomy and 12.2% of those undergoing conservative treatment.

Moreover, these types of complications were significantly more common in patients with placenta percreta (38.5%) compared to patients with placenta accreta/increta (9.4%) (36). They were also more common in cases that underwent an emer-

gency intervention (24.6%) compared to cases that underwent a planned procedure (15.4%) (36). These findings highlight the importance of prenatal diagnosis, planned surgical management and appropriate resource allocation, especially for high-risk patients (37-41).

Another retrospective study assessed the incidence of lower urinary tract injury during hysterectomy in 156 cases diagnosed with PAS disorders (42). The authors demonstrated that in the evaluated cohort 32.7% of cases were classified as PAS 1, 20.5% as PAS 2, and 46.8% as PAS 3. Surgical complications were significantly more common in cases diagnosed with PAS 3 (17.8%) compared to cases diagnosed with PAS 1 (0%) or 2 (12.5%). The incidence of lower urinary tract injury was 7.6% in the evaluated cohort and was significantly higher in the PAS 3 group.

In this study, significant intraoperative blood loss was documented in 32.25% of these patients, who benefited from blood transfusions. Shamshirsaz *et al.* conducted a retrospective study evaluating coagulopathy in 123 patients with PAS disorders (43). In the evaluated cohort, 30.1% developed coagulopathy and had an estimated blood loss was 2100cc. The overall number of units of red blood cells transfused was significantly higher in the coagulopathy group.

A recent review that included data from 10 studies evaluated the association of conservative management of PAS (placenta kept *in situ* aims) with the risk of coagulopathy and subsequent bleeding (44). This study outlined a potential risk of coagulopathy when this type of management was employed, and also the presence of a large placenta as a marker of developing coagulopathy.

Another systematic review evaluated the association between disseminated intravascular coagulopathy and conservative management of placenta percreta using data from 11 studies (45). Based on their findings, the authors suggested routine monitoring of the coagulation parameters, and signs of infection during postpartum follow-up in patients with conservatively managed placenta percreta.

This study has several limitations: its retrospective design, small sample size, lack of generalizability and limited number of ultrasound markers analyzed, reflecting our experience from a single center. Further studies, focused on developing predictive models that will include clinical risk factors.

CONCLUSIONS

Placenta accreta is considered a life-threatening condition and a dreaded pathology for obstetricians, particularly in level two hospitals with limited blood supply. It is also the leading cause of maternal mortality, postpartum hysterectomy, and ICU admission.

Ultrasound screening for PAS disorders should be performed in all patients with known risk factors. Our results showed that placental lacunar spaces, myometrial thinning of less than 1 mm and bladder wall interruptions achieved the highest accuracy in predicting PAS disorders. Moreover, the best predictive performance for predicting PAS disorders was achieved when using at least three ultrasound markers

When considering the surgical team, it should include an experienced obstetrician, a urologist, and even an available general surgeon, if needed. If hospitaliza-

tion is planned, it is important to cross-match and prepare the blood type. Suggest the elective caesarean section at 37 weeks' gestation maximum, after completion of antenatal corticosteroid treatment for lung development.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.
